Infrared microspectrophotometry is a combination of two techniques – optical microscopy and infrared (IR) spectrometry – which supply specific information about the composition and structure of a given material. The equipment used is a Fourier transform infrared (FTIR) spectrometer connected on line with an optical microscope.

The microscope allows observation of a sample in white light at relatively high magnification; this allows its morphology and microstructure to be established, and facilitates selection of the area which will subsequently be subjected to IR spectrometric analysis. The microscope also permits use of polarized light in investigations.

The spectrometer enables analysis of a sample with a chosen measuring technique – transmission or reflection – with the aim of determining the chemical composition of the sample. It also supplies information about its microstructure and orientation.

This method is particularly useful in the analysis of trace amounts of various substances secured as material evidence in court cases, and in analysis of the homogeneity of the sample, identification of inclusions and contaminants on the surface, and detection of structural defects.

A specific advantage of this method is its ability to unambiguously photograph and record marked and measured areas of the sample and minimize the process of preparing the sample for analysis.

Furthermore, IR microspectrophotometry gives the rare opportunity of studying small crystals or areas in the oriented materials by using polarized IR radiation, both by the transmission and the reflection technique.

Its fundamental drawback is that the physical nature of the microsample may influence the precision of the photometric measurements and cause distortion of the spectra (artefacts) obtained. Furthermore, because only a small area is studied the heterogeneity of the sample and the amount of contaminants may significantly influence the results of spectrometric measurements.

Microspectrophotometry in the ultraviolet/visible (UV/ VIS) range is a combination of photometric measuring techniques and optical microscopy. It allows comparison of the color of very small samples of various materials, such as single fibers, tiny amounts of paint, traces of ink or ball-point pen ink on a forged document in an objective way, independently of the sharpness and quality of the observer’s vision. It yields immediate information about spectral differences existing between two samples of similar color, which are indistinguishable by use of the optical microscope. Additionally, using appropriate software to analyze the results of microspectrometric measurements, it enables precise measurement of a color, and – applying the theory of colors – gives a color a defined numerical value; this facilitates communication between experts working with this method. The equipment consists of an optical microscope with a spectrometer for analysis in the visible and ultraviolet range, connected to a microcomputer via an analog-to-digital converter.

1 INTRODUCTION

Microspectrometry is a new method applied in chemical microanalysis which has simplified the procedure for preparing and studying samples in a fundamental way.

Microspectrometry is a combination of optical microscopy and spectrometry. Microscopy deals with creating, recording, and interpreting magnified images, and spectrometry makes use of emission, absorption, and reflection of radiation energy through materials to determine their structure, properties, and composition. Both methods have been developed from optics and the action of radiation energy on matter. Microspectrometry is divided into IR and UV/VIS, according to the type of energy used.

IR microspectrometry enables determination and comparison of composition of examined samples, whereas
UV/VIS microspectrometry serves to establish and compare colors of analyzed samples in an objective way, independent of the observer and the quality and sharpness of human vision and perceived color.

The fundamental advantages of microspectrometric techniques are the possibility of studying relatively small amounts of sample, eliminating the burdensome process of preparing the sample for study and the ability to repeat measurements without destroying the sample. These advantages have led to these methods being used today in most forensic laboratories in the study of traces revealed at the crime scene.

2 ANALYSIS OF CHEMICAL CONTENTS
BY INFRARED MICROSCOPETRY

2.1 History

IR microscopes for dispersive spectrometers were developed in several academic laboratories in the late 1940s and early 1950s but were used by only a handful of researchers. Even when Perkin-Elmer introduced a commercial unit in 1953, few people applied it in research work. In the late 1970s, FTIR spectrometers were developed. The virtues of the new type of instruments, such as higher resolution, lower noise and better frequency accuracy than that of the ubiquitous dispersive instruments, allow the application of the microscope attachment.

However, the IR microscope attached to the FTIR spectrometer tends to restrict throughput (Jacquinot). The optical throughput of an optical system is described by Equation (1).

\[ \frac{A}{q} \times \frac{D_s}{\theta_D} = A \Omega_s \]  

where \( A \) is the area and \( \Omega_s \) is the solid angle subtended by the limiting aperture of the system (in the FTIR microscope, this would be the area-defining aperture). Because a microscope is by definition used for small samples, the sample area contribution to the throughput calculation is reduced. So, one tries to increase the solid angle as much as possible, in order to improve signal and spatial resolution. One normally still ends up in a region where more optical throughput is attained than by a dispersive spectrometer.

By 1982, the sensitivity of IR spectroscopy had been developed to a point where low-energy and microscopic techniques were again being tried. Today, FTIR microscopy is the chosen technique for a wide range of sampling problems. The first microscopes only enabled transmission spectra to be obtained. Today one can also register reflection spectra. The type of sample studied usually determines the study technique chosen.

2.2 Technique Evaluation

It would be a gross oversimplification to claim that all you need to do to perform IR microspectrometry is to place the studied sample on the microscope stage in a beam of IR radiation and carry out the measurements.

Because all studied samples are unique, especially those which are the subject of forensic investigations, the optimum method of analysis must be used, encompassing the following: choice of the appropriate microscopy technique, preparation of the sample to be studied by that technique, selection of instrument, study of the area of sample for analysis, measurement of the spectrum in chosen area, interpretation of results of analysis and correlation of these results with the microstructure of the sample.

To gain a good quality IR spectrum two measuring conditions must be fulfilled:

- IR radiation energy reaching the detector must be very high (high throughput);
- the area of the sample analyzed spectrometrically must be strictly defined.

Nonfulfillment of these conditions leads to lowering of the signal-to-noise ratio (S/N) which leads to such phenomena as radiance, diffraction, and aberration, causing optical noise. A similar thing happens in the case of irregular lighting of the field of vision and measurement. It is easy to define the area of a sample which interests the analyzer, using a beam of white light. The area which will be analyzed by IR is larger as a consequence of diffraction of the IR radiation. Consequently, with a smaller sample, an exact delineation of the area for spectrometric research becomes critical in order to achieve a good spectrum. A badly defined area of the measured sample results in a bad spectrum. In such a situation apertures that limit the field of vision are helpful, being located between the source of radiation and the sample, and also between the sample and the detector.

Initially, IR spectrometry was applied to the analysis of very small (nanogram) samples. Today the method is frequently used in the analysis of small areas in large samples, because they can be isolated selectively using apertures, without the need to prepare additional specimens. Measurements can be carried out by reflection and transmission techniques.

Measurement of reflection spectra in IR microspectrometry is the best method with which to analyze surfaces, thin films, and strongly reflecting or dispersed materials. It does not require preparation of the sample for study and does not cause destructive changes to the substance studied. The spectra obtained by reflection do, however, generally differ from transmission spectra in
shape, outline, and intensity of bands. It is therefore necessary to correct the spectra using the Kramers–Kronig transformation. Depending on the type of sample studied the following reflection techniques can be applied:

- specular reflection
- diffuse reflection
- attenuated total reflection (ATR)
- reflection–absorption.

The transmission technique is characterized by excellent photometric accuracy and introduces the least spectral interference during measurements, so it has been applied in quantitative analysis. However, its fundamental drawback is the necessity to prepare samples for study. The aim of preparation is to separate the studied sample from the surface on which it is found and to obtain the appropriate thickness. Many traditional techniques applied in the preparation of samples for microscopic investigations can be used unchanged, or with only slight modification in IR microspectrometry.

A thin sample is obtained for transmission investigations by cutting the specimen, for example by using a microtome, abrasion and polishing, crushing, flattening through rolling out, or the use of a diamond cell anvil and grinding and pressing tablets with potassium bromide (if the morphology of the sample is not interesting). The ideal sample for transmission investigations is transparent, 1–10 µm thick, and positioned on a KBr plate to eliminate potential sources of error. In some cases transmission of IR radiation is accompanied by specular and/or internal reflectance. This effect can be eliminated by arranging the sample between two KBr windows or immersing it in immersion oil. In the case of samples suspended in KBr, if the size of the sample grains is comparable with the length of the IR radiation wave, then scattering radiation occurs.

The quality of the spectrum gained by IR microspectrometry may be influenced by the thickness of the sample, the averaging of the signal and the optical resolution.\(^{(3–5)}\)

The S/N may be improved by changing the thickness of the sample, or by performing measurements for a large area of sample or for a thick sample, so that the absorption bands have an intensity of about 0.8. The level of noise can be reduced by carrying out many measurements and averaging them as the S/N is proportional to time spent conducting measurements. In routine studies a resolution of 8 cm\(^{-1}\) is most commonly applied.

Sometimes, good quality spectra can be obtained by the microscope technique for nanogram amounts of samples, i.e. amounts which cannot be analyzed by other IR spectrometric techniques. However, one must be aware that the physical nature of microsamples may cause distortion of the absorption bands or influence the photometric accuracy. Thus, minute pieces that are analyzed microtransmissionally, such as individual bits of paint or fabric, have their own geometric shapes that will influence the spectral data collected. The effect of dispersed light is visible on these spectra, especially clearly in the case of strong bands. It is then necessary to flatten the sample, reduce the size of the aperture or analyze by microreflectance.

As a result of radiation dispersion, thick-grained powder samples give spectra with a sloped baseline, especially in the case of shorter waves. It is then advisable to correct of baseline. However, as a result of the Christiansen effect in the fingerprint area, bands appear with sides going down below the baseline. Then it is essential to prepare tableted samples with KBr. A problem that occurs when optically analyzing nontransparent tablets is stray light effects. In such situations the thickness of the sample must be reduced.

Every feature of a spectrum – the size, shape, and position of peaks, and even the nature of the baseline – contains information concerning the sample. Not every feature, however, is related to the chemical structure of the sample, as some arise from optical phenomena. Therefore spectra should be obtained and examined with a view to identifying these spectral artefacts (interference patterns, stray radiation) so that in comparative work the possibility of a false negative conclusion being drawn is minimized.

The recently introduced ATR microscope objective has the significant advantage of allowing the analyst to view the specimen directly where the measurements are taken.\(^{(4)}\) This method is nondestructive and generally allows the analysis of specimens in situ, on evidence such as garments or documents.

Another advantage of analysis by IR microspectrometry is the possibility of examining microscopic contaminants in chemical systems and observing the homogeneity of the composition of the studied sample both on the surface (by way of mapping) and deep within the sample (by so-called depth profiling).\(^{(6)}\) For these techniques to be performed it is essential for the microscope to possess a motorized stage, allowing automatic moving of the sample by a defined distance over several micrometers. Measurements can then be performed for a chosen defined area of the sample at set intervals, such as every 10 µm, effectively providing a series of IR spectra. These spectra can be presented on a three-dimensional system of coordinates, namely the wavelength, absorption, and position of the sample. This gives a three-dimensional array of spectra, illustrating the variability of composition of the studied area of the sample. On this basis a compositional contour map can be prepared, which ensures that
a more exact picture of the distribution of a selected component in the sample is gained. This procedure is often used in studies of heterogeneity or defects of structure of polymer laminates.

2.3 Microspectrometry in Forensic Work

The basic advantages of IR microspectrometry are:

- use of picogram or smaller samples;
- unambiguous identification and photographing of measured areas of sample;
- archivization of measured areas;
- elimination of the burdensome process of preparing the sample for research;
- repetition of measurement (nondestructive analysis).

These make the technique especially useful to forensic studies, such as in the identification of microtraces, namely paint chips, fragments of polymers, rubber, glue, and single fibers. This type of material is secured for study from the scene of the event, most frequently a road accident, break-in, rape, or homicide. This technique is also used in the analysis of chemical composition of inks and toners, used in the forging of documents.

2.3.1 Examination of Paint Fragments and Laminates

The authoritative reviews are given by Messerschmidt\(^7\) and Humecki.\(^8\) Ryland\(^9\) and Suzuki\(^10\) have published comprehensive bibliographies of applications, including paint examination.

In routine comparative examinations of paints, transmission IR techniques are mainly used\(^{11–16}\) to provide information about binders, pigments and additives used in various types of coatings. Because usually only a small amount of sample is available for study, up to now little bits of paint have been prepared for study using microtableting methods with KBr or a diamond cell anvil. The IR beam is focused on the microtablets or the diamond cell using a beam condenser. Nowadays, a microscope attachment is used.\(^{17–28}\) IR microspectrometry is one of the most valuable tools of the forensic paint examiner. It allows highly reproducible nondestructive individual layer comparisons with a very limited time investment.

Microfragments of car paint found on a road or revealed on the clothes of a victim of a traffic accident are usually multilayer fragments of paint. A sample of an individual layer may be prepared manually using a scalpel, blades, or needles, and then placed on a salt plate for analysis. Samples also can be obtained for spectrometric investigations by cross-sectioning the multilayer coating. A fragment of paint may be cut into slices 2–5 µm thick, using a microtome perpendicular to the surface. The specimen gained in this way is then placed on the microscope stage and its morphology is observed, i.e. the number, thickness, color, and grain of the layers visible on a cross-section of the fragment. Then, limiting the field of vision with the microscope aperture, the fragment’s IR spectrum is determined for only one layer using the transmission technique (Figures 1 and 2). Comparison of the spectrum with library spectra provides information about the type of paint in the layer, i.e. the type of resins occurring in the binder and the basic pigments. This same specimen may be used in further studies, such as with a scanning microscope linked to an X-ray microspectrometer for determining the elemental composition of particular layers, and for identifying all inorganic components (pigments, fillers). Instead of preparing the specimen using the microtome, fragments of paint are flattened in the diamond cell anvil, and then positioned on the stage of the microscope in the path of the IR radiation. Samples of polymer laminate are prepared for research and analyzed in a similar way.

Paint and polymer microtraces transferred from a car to the clothes of victims of traffic accidents are studied using the IR microspectrophotometry method. They are visible macroscopically as colored streaks. However in the microscopic image, bits of material can be observed which have been “rubbed in” or melted in-between fibers of the fabric. For identification of the transferred material and possibly comparison with material taken from the car of the person suspected of participating in the accident, it is necessary to separate microflakes from the surface. Microflakes that have been separated out are positioned directly on the KBr plate lying on

![Figure 1](image-url)
the microscope stage and a spectrum is collected in transmission mode. Study of the microtraces by the reflection technique directly on the fabric frequently does not give satisfactory results, because the absorption bands of the fabric may mask the absorption bands of the material being investigated.

Transfers of coatings resulting in smears on other substrata may be sampled in situ using an ATR objective on an IR microscope. As a control, the substratum should also be analyzed to verify that its absorption bands are not contributing to the spectrum of the smear.

In comparative studies of paint samples, the reproducibility of the method of study is of fundamental significance.\(^9\) If it is weak then differences observed between spectra of samples of the same paint coat (resulting from its natural variability) can be interpreted as significant differences, wrongly indicating that the analyzed samples were different and originating from various objects. Conversely, if the differences between spectra of samples of different paint coats (variability between samples) are of the same magnitude as the differences in spectra obtained for the same sample, then one might wrongly conclude that the samples studied were identical and so originating from one source.

This technique is in most cases repeatable but, because it is in principal a point analysis, it is necessary to carry out several measurements for several micro-areas of the same sample. It is worth adding that the reproducibility of the measurements is influenced by the fact that the paint is heterogeneous. This has no significance in analysis of macrosamples, but if measurements are carried out for microfragments when using an aperture smaller than 100\(\mu\)m\(^2\) it becomes critical. Reproducibility depends on the technique of preparing the sample for measurement. The most popular method of flattening a sample, by pressing and squashing it, introduces orientation in polymer molecules and changes their crystallinity. There is no one single universal technique for preparing a sample. It depends on the type of sample. For example, problems encountered when studying paint transfers can be due to difficulties in separating the sample from the surface on which it was found. Subtraction of spectra usually does not provide good results.

Using microspectrophotometry, both the binder and pigment portions of the paint are represented in the data obtained, allowing quick eliminations without the use of multiple instrumental techniques. Microspectrophotometry is quite discriminating for most binder types, especially those employing copolymer modifications. This technique is also sensitive to changes in organic pigment composition. However, IR microspectrometry has its limitations and should not be the sole instrumental technique used for a full comparison of the evidence and a standard sample. IR microspectrometry does not provide sensitive detection of minor components. Constituents present in concentrations less than 5% will typically go unnoticed. The problem of poor sensitivity to minor components is not limited to organic compounds. Thus broad band nonorganic pigments, which are present in low concentrations, will be masked by the major inorganic extenders or organic binders, especially in the region 700–2000 cm\(^{-1}\). Furthermore, there are some types of binders whose IR spectra change very little from one to another. The presence of high concentrations of extender pigments can cause problems in binder comparisons and classifications. Additionally, not all extender pigments have similar compositions, yet different crystalline forms can be differentiated by IR spectroscopy.

In summary, IR microspectrometry is a fast, nondestructive technique allowing individual layer comparisons on casework-sized samples. It can provide information about both the binder and the pigment portions of a cured paint specimen, as well as their relationship to one

another. It possesses the ability to discriminate between a great number of paints having similar colors and similar binders.

2.3.2 Analysis of Single Fibers

Microspectrometry is used in analysis of microfibers conveyed from fabric to fabric or other surface as a result of contact between the two. For a single fiber of length 1 mm one can obtain an interpretable IR spectrum by the transmission technique, on condition that the fiber is sufficiently thin and transparent for IR radiation.\(^{(29–37)}\)

The way in which a fiber is prepared influences the fine detail of the spectra obtained.\(^{(38)}\) Squashing of the fiber is essential to ensure that sufficient energy is transmitted through the fiber substance. To get reproducible results the technique of squashing needs to be reproducible. Thus, in any one laboratory it will be necessary to build up a library of spectra from authenticated samples against which spectra from case materials can be empirically compared.

There are many methods of preparing and mounting fiber samples for analysis by IR microspectrometry. The choice of method depends on the individual analyst, the particular requirements of the laboratory, and whether or not subsequent analyses may be required.

Unflattened fibers may be mounted across an aperture or placed on a KBr window and analyzed directly. The aperture may be a hole in a metal disk with the fiber mounted on double-sided adhesive tape. This method has two major disadvantages. First, fibers greater than 50 µm in diameter are generally too thick for obtaining good-quality spectral data. Fibers with circular cross-sections have a variable path length and act like a lens because the beam passes through the sides and the center. Under these conditions the ratios of less intense bands to stronger bands are greater than those obtained with a uniform path length. Second, circular and irregular cross-sectional shapes tend to diffract and scatter incident IR radiation. In general, the use of unflattened fibers is good for obtaining initial spectra of weaker crystalline bands. The fiber should subsequently be flattened by some means to obtain a good overall spectrum. Note that crystallinity changes may occur during fiber flattening and the spectra may be slightly distorted.

Flattening the fibers prior to analysis offers several advantages. Deviations from Beer’s law are reduced because samples have more uniform thickness. The reduction in path length is also important for fibers possessing high absorptivity. Additionally, flattening increases the surface area of the sample available for analysis, thereby enhancing S/N while reducing diffraction effects at the fiber edges.

Fibers may be flattened with a roller knife or between plates in a laboratory press. Fibers may be placed between two KBr disks and compressed with a compression cell or a diamond cell anvil may be used, which involves sandwiching a sample between diamond windows.

However, flattening destroys the physical shape of the fiber. In addition, the application of pressure can change the crystalline composition of the polymer. Although no major spectral differences have been observed as a result of applying pressure to fiber samples, minor changes in peak frequencies, intensities, and shapes do occur for certain fibers.

Flattening fibers on a hard surface also effectively produces a thin film and may result in interference fringes in the IR spectra. These fringes do not interfere with qualitative interpretation of the spectra, but they can affect quantitative analysis and comparisons made with large databases.

The polymer composition of the fiber is identified on the basis of analysis of IR spectra, and then classified (Figure 3). When results of other investigations, i.e. color and morphology, are also taken into account, the fiber can be identified. Contaminants occurring on fibers can also be identified by microspectrometry.

In certain instances, the presence of a contaminant can increase the evidential value of a fiber match when the contaminant is shown to be present on both the questioned and known fibers. The technique is useful in the identification of man-made fibers.

To sum up, IR microspectrometry is quick, nondestructive, highly sensitive, and provides a wealth of information from a short piece of single fiber. Every feature of a spectrum contains information concerning the sample. Not every feature, however, is related to the chemical structure of the sample. Certain features, such as interference patterns and stray radiation, may arise from optical phenomena.

\[\text{Absorbance} = \frac{\text{Transmittance}}{1} \]

\[\text{Wavenumber (cm}^{-1}\text{)} \]

**Figure 3** IR spectra of different kinds of single Nylon\(^{\circledast}\) fibers.
2.3.3 Examination of Inks

Writing materials, i.e. toners and various types of ink (in the form of text or writing on paper), are also studied by IR microspectrometry.\(^{(30-42)}\) In cases relating to forgeries and suspicious documents, it is often necessary to know whether a questioned fragment of text or signature was created with the same type of writing/printing material as the remaining part of the text; sometimes it is necessary to establish whether an entry was made by the writing instrument sent in for study (Figure 4). In order not to destroy a studied document, the reflection technique can be applied, placing the document under the microscope and limiting the field of vision and measurement to the line of the questioned fragment of writing. However, one rarely gains good results by this method. Experience teaches that a spectrum obtained in this way mainly contains absorption bands of cellulose, i.e. paper, which masks the absorption bands originating from the ink or toner. It is more advantageous to separate out a fragment of writing agent with a scalpel and, after conveying it to a KBr plate, to obtain a spectrum by the transmission technique. That is the procedure for ball-point pen inks and toners. The loss of this agent in the line of writing is then minimal, invisible to the naked eye. In the case of some types of agents (e.g. inks for fiber pens) it is necessary to cut out a several millimeter long line of writing from the studied fragment of text and to carry out microextraction of the sample of ink or paste from the paper, using a mixture of solvents. The extract is then studied by the transmission method after being placed on the KBr window lying on the microscope stage. Independently, thin-layer chromatography may be used.

The reflection technique is successfully applied in the study of banknotes, tickets and other special forms where the layer of printing ink deposited on a significant area of the paper is sufficiently thick. Then absorption bands originating from the material deposited on the surface and not from the paper (the base of the document) are visible in the IR spectrum. Then it is especially useful to use a microscope with an ATR objective. Spectra can be obtained in several minutes without the need to remove the agent from the document.

The recently introduced ATR microscope objective has the significant advantage of enabling the analyst to view the specimen directly where the measurements are taken. The method is nondestructive and generally allows the analysis of specimens in situ on the evidence, i.e. on the document.

2.3.4 Others

2.3.4.1 Hair

Hair is often found at the scene of the crime. The IR spectra of hairs are not readily distinguishable between individuals. However, the presence of hair spray or other coatings on hair (Figure 5) can significantly increase the value of evidence.\(^{(4)}\)

2.3.4.2 Oils

Another type of trace is so-called greasy stains, revealed on the clothes of victims of road accidents as a result of contact with a vehicle’s chassis bearing oil or lubricant, or on the clothes of an arsonist. Stains visible on the fabric of the clothes may be of varying size; however, barely a drop (of oil or other lubricant) can be

![Figure 4](image_url)  
**Figure 4** IR spectra of different kinds of black toners.
obtained by extraction with solvents. This small amount of substance can only be analyzed by IR spectrometry if the microscope attachment is used. In order to take a measurement using the transmission method the sample is deposited on a KBr plate; for measurement by reflection it is placed on a metal plate. Comparison of the spectrum with the catalog of spectra of oil products sometimes enables identification of the lubricant. More frequently the spectrum obtained serves to establish the degree of similarity of the material forming the stain and the material secured from the vehicle of the suspect (Figure 6).

### 2.4 Raman Microspectroscopy

Raman and IR microspectroscopy are two complementary techniques. Whereas IR spectra are the result of absorption of radiation, Raman spectra arise from an inelastic scattering effect. The selection rules differ for IR and Raman. The bands that appear weak in the IR spectrum will be strong in the Raman spectrum, and vice versa.

There are only a few data in the literature on the subject of using this technique in the study of fragments of paint coatings. It is interesting that some paint components may have vibrational modes that produce no IR absorption bands, but may produce Raman bands.

Raman spectroscopy is used increasingly in the study of fibers. The Raman technique is sensitive enough to analyze single fibers readily with microscopes coupled to spectrometers. In addition to the complementary vibrational information obtained, Raman spectroscopy offers several other advantages. First, sample preparation is eliminated because scattering and not transmission is measured. Second, diffraction effects are greatly reduced because the exciting radiation is of a lower wavelength than IR. Third, spatial resolution is enhanced. Finally, narrow-range IR detectors generally have a low-frequency range near 700 cm\(^{-1}\), whereas Raman experiments are generally performed down to 200 cm\(^{-1}\).
and new holographic notch filters are pushing this limit down to 50 cm⁻¹. In this far-IR region one can find information relating primarily to the inorganic components of fibers, such as delusterants. Because Raman spectroscopy is not a transmission technique, fibers do not have to be pretreated before analysis, but there is potential for the surface composition of the fibers to be over-represented in the spectrum.

2.5 Databases and Libraries

The high repeatability which characterises the IR microspectrometry method enables the creation of libraries of spectra of samples of various materials as well as computer databases containing (in addition to catalogs of IR spectra) data on the subject of morphology, structure, physical and optical properties of materials and also technological data. They help to identify and classify samples quickly. Libraries of spectra formed in one’s own laboratory are best suited to these aims, which reflect the influence of local factors on the spectrum, such as the equipment, sample preparation method, the measuring technique, and the measuring conditions. Specialized firms offer libraries of IR spectra for sale. These are most frequently catalogs of the spectra of polymers, pigments, and other pure ingredients used in production of paints, fibers, writing agents, and other materials (Sadtler, Hummel, Aldrich). They are also available on diskette or CD (e.g. Nicolet, Spectra-Tech.).

It is more difficult to obtain databases of ready-made products, as opposed to the individual component materials. Catalogs of automobile paints (such as the Collaborative Testing Services (CTS) automotive paint collection) or fibers (such as the CTS fiber collection) do exist, but they only cover a few thousand samples of materials produced in a defined period of time (10–20 years).

Databases are being created by forensic laboratories in some countries. These encompass the products encountered or produced in a given country. The creation of a full and current catalog of products produced around the world is almost impossible, as this would require permanent cooperation of all manufacturers worldwide with research laboratories.

To sum up, IR microspectrometry has made it possible to identify and detect picogram quantities of some chemical substances, eliminating the need for previously applied techniques of sample preparation, which required a lot of time and effort. Together with optical and scanning electron microscopy, the method has become an indispensable tool in forensic research for the identification of trace amounts of various materials. When interpreting the IR spectra gained by this method it should be borne in mind that IR spectra obtained for nanogram quantities of unknown samples may not be the spectra of just the samples under investigation, but those of ubiquitous contaminants, such as fragments of epidermis, dust, or wood dust, which may be identified, respectively, as a fiber of Nylon®, silicon, or cellulose. By analyzing microregions of heterogeneous samples in a similar way, different IR spectra can be obtained at various places on the same sample. Repeated measurements for a given sample are therefore recommended.

3 COLOR ANALYSIS BY MICROSPETROPHOTOMETRY

3.1 History

The first microspectrometers were built in the late 1950s by individual laboratories. They were made for the purpose of measuring absorption spectra of colored fibers, for the types of traces which were frequently secured in connection with crimes at the time. These instruments consisted of a monochromator or filtering device as the source of light, a microscope, and a sensitive photometer. They were built because microscopic comparisons of two fibers could only reveal that “the fibers are similar”, or “the colors match”, which was insufficient for courts. Furthermore, in the case of analysis of very short, millimeter-long fibers it was not possible to identify the dye by thin-layer chromatography.

Today most laboratories use microspectrophotometers which are produced by specialized firms. A microspectrophotometer system has as its component parts a microscope, a spectrophotometer, a control unit for the photometer (a spectral data processor), and a chart recorder or plotter. Many users also incorporate as part of their system an analog-to-digital converter to interface with the microcomputer. The photometer is mounted on a microscope and consists of a grating monochromator and photomultiplier detector.

Analysis of the color of materials for forensic purposes was introduced in Europe at the beginning of the 1970s, especially in Switzerland where it was routinely used in the analysis of fibers. Only at the end of the 1970s was this technique tested and its discriminating power assessed. In 1979 Macrae analyzed blue woollen fibers with the help of a comparison microscope and the microspectrophotometry method. He stated that in studying fibers using a comparison microscope the discriminating power was 68%, whereas for measurements made by microspectrometry it was 99%. It also turned out that in some cases it was possible to distinguish fibers by thin-layer chromatography, although when using microspectrophotometry in the visible range they were indistinguishable.
and vice versa. Both techniques are currently considered complementary in the analysis of fiber color.

The effectiveness of discrimination by microspectrophotometry was also checked in the case of cotton fibers.\(^{(53)}\) For red cotton fibers, 320 out of 1035 pairs of fibers could not be distinguished by microscopy, but only 20 could not be distinguished by microspectrophotometry. The fact that microspectrophotometry is highly discriminating and nondestructive, and that when using it spectra can be gained, even for very small microfibers or little bits of other materials, means that UV/VIS microspectrophotometry has begun to be universally applied in forensic laboratories.

3.2 Spectral Measurements and Analysis

Color is an essential feature of materials which is taken into account in comparative forensic studies.\(^{(38,51)}\) A visual description of color, especially a comparison of the color of two objects, is difficult because the human eye only sees within a narrow range of electromagnetic radiation (the so-called visual range), and even in this range it is not uniformly sensitive to the energies of all wavelengths. The color of an object also changes depending on the lighting and background. So lighting, background, observation conditions and a good observer are prerequisites for a good observation of color, essential for an accurate comparison of the color of two samples. In order for a color to be measured objectively, it was necessary to find a method of description of color which would correlate with its visual perception.

Color is linked with absorption of incident radiation. According to Beer’s law absorbance of a material is linearly related to its concentration. Hence colorimetric methods have been used for years to define it. The new generation of spectrophotometers for the visual range, which measures transmitted or reflected light by a sample, is universally used in the measurement and comparison of the color of two objects.

The color of an object depends on three factors: the light source, the observed object, and the color response of the eye. Visual descriptions of color are very subjective, and simply recording absorption maxima alone will afford only limited information. A number of color order systems have been developed, which are of great value for storing and communicating color information. The method developed by Peterson and Cook\(^{(54)}\) was based on a widely accepted color ordering system originally proposed by the Commission International de l’Eclairage (CIE) of 1931.\(^{(38,55)}\)

Each shade of color can be obtained by mixing the three basic colors in appropriate proportions, namely red, yellow and blue. Every color is therefore a function of three variables. This can be expressed mathematically as a system of linear equations. These allow the calculation of so-called chromaticity coordinates from the tristimulus values. Appropriate coefficients of proportionality are worked out by experiment.\(^{(51)}\) A digital code is ascribed to each color, so that instead of a verbal description of the color an unambiguous digital description is introduced. Color catalogs have also been developed that are used by experts and facilitate understanding between them.

A color comparison is carried out on the basis of results of spectrometric studies, taking into account the position of maximum absorption on the spectrum and the course of the graph over the whole spectral range. The wavelength corresponding to maximum absorption and the sum of squares of the differences between points on spectra corresponding to each other may be differentiating parameters.

3.3 Application in Examinations

There is a constant need in forensic science for comparison of colors to establish identity between two parts and, as the difference between identity and nonidentity may be very small, great care must be used to convince a court. Usually the samples are small – such as a hair, a fiber, or a paint chip – so special apparatus is needed. For straightforward comparison a comparison microscope with two fields is used, but when the color, as seen by the instrument, must be recorded, a specialized colorimeter or spectrometer is used.

Many forensic laboratories worldwide have successfully used microscope-mounted spectrophotometers to compare fibers and other materials such as inks, paints, and plastics.

Microspectrophotometry, which uses a microscope and photometric measuring techniques, has proved to be an extremely valuable, if not indispensable, tool in comparing the colors of fibers.\(^{(53,55–58)}\) With its ability to provide color information from very small areas of single fibers, microspectrophotometry can confirm suspected color matches while removing the disadvantages of subjectivity which are associated with human perception of color. Equally important is the ability of microspectrophotometry to immediately inform the user of spectral differences between two colored fibers, in spite of a convincing visual match on the comparison microscope – the phenomenon known as metamerism.

The examiner of a questioned document is faced with the problem of identification and comparison of inks which are apparently similar in color and shade. Inks are characterized by various physical, chemical, and chemophysical techniques. Nondestructive optical methods do not always reveal the identity of individual ink components and may not be entirely conclusive.
Visual examination with or without the aid of a microscope is operator dependent and lacks the sensitivity and precision of spectrophotometric instrumentation. Application of microspectrophotometry, however, enables examination and comparison of different kinds of inks. Nowadays color measurement in document examination has to be performed on ink traces and occasionally on small fibers such as those found in banknotes. This requires a microspectrophotometer with capabilities in transmission, reflectance, and sometimes fluorescence modes.

An object to be examined, such as an ink line, is viewed through a microscope and the light reflected from it is measured over the visible spectrum. The reflected energy is then compared with a standard stored in the system’s microprocessor, and a spectral curve is provided which is characteristic for the color of the object examined. Visible spectra have been measured from minimal quantities of commonly encountered ball-point and fiber-tip pen inks. Comparison of these spectra provided a high degree of discrimination between similarly colored inks.

More recent applications in document examination should find increasing application in the authentication of passports, visas, green cards, credit cards, money orders, international banknotes, and many other valuable or critical documents. This procedure has been applied to the detection of forgeries in documents by showing up the difference in color of ink in different parts of a document, whether handwritten or typed. Even if an addition or alteration has been made with the same ink at a later time, this will show and be recorded, because color changes at a regular pace as a result of atmospheric oxidation.

Another application is in the confirmation that a particular paint chip came from a particular car, or even to identify the make of car from which a chip originated. Microspectrophotometry may be required to provide objective color data for paint comparison due to the typically small size of samples. The technique can be applied to the outer surfaces of paint films by diffuse reflectance measurements with visible spectrum illumination. Comparison of paint layers by transmission microspectroscopy of thin edge sections offers a more definitive form of color analysis for these samples compared to reflectance techniques. Individual makers have a standardized procedure of a number of undercoats and topcoats. A microscopic examination of a cross-section of the chip with a measurement of their colors can identify the make, and, furthermore, pin down an individual car, if an authentic sample is available for comparative examination.

The application of this technique in forensic research is a relatively new development. In the case of very small samples of paint it is irreplaceable in defining and comparing colors. Although up to now no research has been published indicating an improvement in the differentiation of samples using UV/VIS microspectrophotometry, this technique shows promise for the compilation of databases targeted at vehicle make/model finish identifications.

### 3.4 Spectral Analysis Using Ultraviolet Radiation and Fluorescence

Interest is growing in microspectrometry in the UV region. Some spectrometers enable the measurement of spectra in the 240–760 nm range, and even 190–900 nm. They can be adapted to the recording of fluorescent spectra. These techniques are particularly valuable in comparison studies of fibers. Fibers which cannot be differentiated in the visible region can sometimes be distinguished in the UV range, especially when the differences relate to the presence or absence of optical brighteners or application of different brightening agents.

Fluorescence microscopy of thin cross-sections, as an aid in differentiating samples or various layers within intact paint fragments, is discussed by Stocklein and Tuente. When using an excitation wavelength of 365 nm, the technique may be sensitive to differences in organic pigments, additives, and film-forming components.

### ACKNOWLEDGMENTS

I wish to gratefully acknowledge the assistance of Zuzanna Brożek-Mucha who proofread various versions of this manuscript and offered valuable suggestions. I would like to thank Małgorzata Pomianowska for help in preparing the figures for this manuscript.

Nuclear Magnetic Resonance Spectroscopy for the Detection and Quantification of Abused Drugs

Brian Dawson
Bureau of Biologics and Radiopharmaceuticals, Therapeutic Products Programme, Ottawa, Canada

1 Introduction

Nuclear magnetic resonance (NMR) spectroscopy provides the forensic analyst with an extremely powerful tool for the detection and quantification of abused drugs. A whole range of one-dimensional (1-D) and two-dimensional (2-D) NMR techniques is available for performing the required analyses. These NMR methods may be used for routine purposes, such as to confirm the identity of a drug or quantify the amount of illicit substance present in a police exhibit. However, the area where NMR stands out as an analytical tool is in the identification of unknown compounds, such as “designer drugs”. NMR is also used in police intelligence work, as it can provide clues to the synthetic route used to prepare the drug. This is done by impurity profiling or by determining the drug’s optical purity. Although NMR has been used for many years to analyze abused drugs, even the most modern spectrometers lack the sensitivity obtainable by other techniques such as mass spectrometry (MS) or high-performance liquid chromatography (HPLC). However, NMR is a nondestructive technique which provides essential structural information which cannot be obtained from these other methods. NMR also has the distinct advantage of not requiring reference standards for the identification of unknowns.

1 INTRODUCTION

The nuclei of atoms with an odd number of protons, neutrons, or both, have an intrinsic nuclear spin. The spinning of charged particles, the circulation of charges, produces a magnetic moment along the axis of spin. The simplest nucleus possessing a spin is the proton, the nucleus of the hydrogen atom. If hydrogen atoms are placed in an external magnetic field, their magnetic moments, according to quantum mechanics, will become aligned in two ways, with and against the field. For hydrogen, the more stable alignment is with the field and energy must be absorbed to “flip” the proton over to the less stable alignment against the field. The amount of energy needed to flip the proton depends on the strength of the external field: the stronger the field, the greater the energy required to produce the flip. The energy required corresponds to electromagnetic radiation in the radiofrequency (RF) range. The observation frequency is given by Equation (1):

\[ v = \frac{\gamma H_0}{2\pi} \]  

where \( v \) = frequency, in cycles per second, \( \gamma \) = a nuclear constant (the gyromagnetic ratio), and \( H_0 \) = strength of the static magnetic field, in Tesla.

When the nucleus is irradiated at an appropriate frequency, absorption occurs, followed by the nuclei re-emitting the RF radiation to return to the lower energy
state. This process gives rise to a signal and the spectrum arising from this signal is called an NMR spectrum. The frequency at which a nucleus absorbs depends on the magnetic field which it “feels” and this effective field strength is not exactly the same as the applied field strength. The effective field strength at each nucleus depends on its environment, e.g. the electron density, closeness of other nuclei, and hence will require a slightly different applied frequency in order for absorption to take place. Thus each different nucleus will give rise to its own signal.

There are two basic NMR spectrometer designs, the continuous-wave and the pulsed or Fourier transform nuclear magnetic resonance (FTNMR). The continuous-wave spectrometers had low-field, water-cooled electromagnets which consumed large amounts of electricity. The newer FTNMR spectrometers use superconducting magnets cooled with liquid helium which consume very little electricity, but require relatively expensive cryogens (liquid nitrogen and liquid helium) to keep them operational. Although continuous-wave spectrometers are perfectly suitable for many routine applications, they have largely been replaced by the higher-field pulsed FTNMR instruments.

Because the energy difference between the nuclei aligned with and against the field is small, the numbers of nuclei in each spin state are almost equal. There is, however, a slight excess of spins in the more stable alignment (of the order of 1 in $10^5$ for protons at 200 MHz). It is the signal from this excess which gives rise to the NMR signal, thus explaining the relative insensitivity of this technique. However, over the last 20 years, the field strength (and thus sensitivity) has grown enormously. In forensic science laboratories, modern spectroscopists can easily obtain good quality spectra on amounts of abused drugs that are much less than a single dose, even for drugs such as mdma and LSD where the dosage is about 50 µg.

Since the results obtained in forensic science laboratories are used in the criminal justice system, the methods used to obtain them must leave no room for doubt. Thus, the analytical techniques used must meet a number of strict criteria. Besides being sufficiently sensitive, they must be highly selective, reproducible, and suitable to give qualitative and, in many cases, quantitative analyses. Other desirable features of analytical techniques within forensic science include that they require the minimum amount of sample pretreatment and that they can handle mixtures of substances without prior separation. As will be seen from the following discussion, NMR spectroscopy meets all these requirements and is becoming more and more important for the identification of unknown substances, as well as for routine analyses, in many forensic science laboratories worldwide.

Reports in the open literature of uses of NMR in areas of forensic interest began with a few papers in the late 1960s. Starting in the early 1970s, reports on NMR results for illicit drugs and some closely related analogs began to appear more frequently. Most of these studies provided forensic scientists with valuable data useful in the identification and differentiation of series of abused substances with varying substitution patterns. These types of papers have continued to appear, often utilizing state-of-the-art NMR techniques and equipment to solve forensic problems such as structures of “designer” drugs. The use of NMR spectrometers in forensic laboratories has become very common since the early 1980s.

2 METHODOLOGY

2.1 Sample Preparation

There is a large variety in the types of samples submitted by law enforcement officers which are amenable to forensic NMR spectroscopic analysis. These include abused drugs, explosives, fire accelerants, hydrocarbon fuels, body fluids and tissues, lachrymators, poisons, and fingerprint reagents. The focus of this article will be on abused drugs.

Illicit drug seizures usually consist of solids (normally powders), plant materials (or their extracts) or dosage forms (tablets, capsules, or elixirs). In most cases, it is only necessary to identify the major component in the sample. However, it is sometimes necessary to quantify the amount of abused substance present. Also, identification of “impurities” in the exhibits (e.g. synthetic by-products, coextracts, decomposition products) may provide police with valuable intelligence information as to the source of the material (e.g. synthetic route used, possible country of origin of the plant).

The methods used to prepare the samples for NMR analyses depend on the source of the sample and the information required. Procedures range from simple dissolution to complex extraction and derivatization reactions which must be done under very stringent conditions.

For the simplest case of “pure” drug, a suitable quantity (usually a few milligrams) of the sample is dissolved in a deuterated NMR solvent. The choice of solvent depends on the solubility of the abused drug. Commonly used deuterated solvents include chloroform (CDCl₃), water (D₂O), dimethyl sulfoxide (DMSO-d₆) or a mixture of chloroform and methanol (CDCl₃/CD₃OD). The amount of sample used depends on the quantity of sample available, the field strength of the spectrometer, and the type of NMR experiments to be performed.
In cases where the exhibit is a mixture, such as in tablets or powders where the abused drug is “cut” with sugar or starch, sample preparation methods depend on the nature of the components. It is often possible to choose a solvent which will dissolve only the drug, leaving the other excipients behind, or to choose two immiscible solvents where the drug will go into one solvent while the excipients go into the other. For example, deuterochloroform will extract many drugs from formulations where the excipients are sugars, since sugars will not dissolve in this solvent but may be taken up in water. In many situations this simple procedure will not work and one must use the chemical characteristics of the drug to separate it from its excipients. Drugs may conveniently be divided into four general categories, acidic, basic, amphoteric, and neutral. For each of these, the partition coefficients between aqueous and immiscible organic solvents differ. The hydrogen ion concentration, which varies with pH in the aqueous phase, affects the ionic state or polarity of the drug, depending on the polar substituents present. It is often possible to separate drugs from different classes from each other or from other organic compounds by proper adjustment of the pH. For example, if the aqueous solution is made acidic, organic solvents may be used to remove acidic and neutral components. On the other hand, if the aqueous phase is made basic, basic and neutral components may be extracted with organic solvents. For amphoteric abused drugs such as morphine, the pH must be adjusted to its isoelectric point for it to be extracted. At this pH, the drug exists in a nonpolar or noncharged form, making it more soluble in appropriate organic solvents than in water. It is possible to isolate or remove neutral drugs or other organic components from acidic and basic drugs by extracting a basic aqueous solution with an organic solvent, and then washing this solvent with aqueous acid. Only the neutral materials should remain in the organic solvent.

When quantification is required, sample preparation procedures are more demanding. First, the amount of sample used must be accurately known. If an extraction procedure is necessary, one must be sure that the drug is quantitatively removed. Next, an appropriate internal standard must be chosen. This standard must meet a number of criteria. It must be pure (or at least be of known purity) and be soluble in the solvent used for analysis. It must be stable and not reactive to any compounds present (including the solvent). For convenience, it is usually easier to work with a solid standard, but if a liquid is chosen, it should be nonvolatile in order to avoid losses during the sample preparation and analysis. Lastly, the standard must have an appropriate NMR spectrum such that both the drug and standard have well separated resonances whose integrals or peak heights may be used in the quantification. It is usually best to choose a standard which has either a suitable singlet or narrow multiplet to minimize the chances of overlap of signal resonances.

Other procedures, such as extraction and derivatization, may be required for different types of plant materials. Special precautions may be necessary when the drugs in these materials are not stable under certain conditions, e.g. in the presence of acid or base. Because of the complexity of the extracts from most plants, NMR is usually not the method of choice for analyzing these materials. However, there have been a few cases where NMR has been used to advantage.

For drugs where legislation refers to only one optical isomer, procedures involving the addition of chiral shift reagents or chiral solvating agent (CSA), or reaction with chiral derivatization agents, are required.

### 2.2 Nuclear Magnetic Resonance Experiments

Since the mid 1980s, advances in NMR techniques have grown dramatically. As the number of experiments increases, most NMR spectroscopists opt to choose a set of these experimental techniques which work well for them in obtaining the kind of information they require. What follows is a discussion of the general types of experiments which have most often been used in the analyses of abused drugs.

#### 2.2.1 One-dimensional Techniques

##### 2.2.1.1 High-resolution Spectra

When most analysts with a passing knowledge of NMR think about this technique, they recall the traditional 1-D high-resolution proton ($^1$H) and carbon ($^{13}$C) spectra. These spectra are highly informative in the hands of a trained NMR spectroscopist. For forensic analysts who may not be experts in the field, these spectra may be used as “fingerprints” for comparison with those for authentic materials. For this type of work, the use of $^{13}$C-NMR spectra is most suitable. $^1$H-NMR spectra are not as convenient for a number of reasons. The main reason is that the appearance of the proton spectra differ significantly when obtained at different field strengths – the higher the field, the more first-order (and thus simpler) the spectra become. At lower fields, the $^1$H-NMR spectra for many abused drugs consist of broad and uninterpretable envelopes of signals, whereas at higher fields the corresponding spectra contain large numbers of sharp resonances which may be readily assigned using modern techniques. On the other hand, $^{13}$C spectra look very similar, regardless of the field strength used. The only difference would be for those signals which may only be resolved from each other at higher fields.
In a routine 13C-NMR spectrum, the signals obtained for DEPT. By suitable choice of experimental parameters, called distortionless enhancement by polarization transfer (DEPT). The best known of these is that which gives a count of the number of protons number of carbons in the molecule. Thus enabling the analyst to get an accurate count of the shifts or if any carbons are coupled to any other nuclei, one can easily determine if there are unresolved carbon shifts provide evidence as to whether the protons are aliphatic (0.8–3.0 ppm), olefinic (4.5–6.5 ppm), or aromatic (6.5–8.5 ppm). Protons attached to carbon atoms that are bonded to nitrogen resonate at about 2.0–3.5 ppm, while if the carbon is bound to an oxygen, the protons resonate at about 3.3–4.5 ppm. Aldehyde protons are found around 8.5–10.0 ppm. Complete tables of chemical shifts may be found in most introductory text books.

High-resolution 13C-NMR spectra also provide a great deal of information. The chemical shift range for carbon is more than 200 ppm. As with protons, the chemical shift ranges are indicative of the kind of carbon. Carbon shifts follow basically the same order as protons, with aliphatic carbons being at highest fields, followed by olefinic and then aromatic carbons. Acid and ester carbonyls are at lower fields than aromatic carbons, followed by aldehydes and isolated (nonconjugated) carbonyls at lowest fields. As with protons, tables of typical chemical shifts may be found in most introductory text books.

The number of carbon signals (excluding those from the solvent) usually gives a direct count of the number of chemically distinct carbons in the molecule studied. Exceptions to this occur when two or more different carbons have chemical shifts that are too close to be resolved under the conditions of the experiment, or when one or more carbons are coupled to another magnetic nucleus that is not decoupled (19F or 31P, for example). In a routine 13C-NMR spectrum, the signals obtained for quaternary carbons are smaller than those for protonated carbons. It is possible, by using longer delays during acquisition and taking care to eliminate the nuclear Overhauser effect (NOE), to obtain carbon spectra such that each carbon gives rise to the same size of peak. When this type of quantitative experiment is performed, one can easily determine if there are unresolved carbon shifts or if any carbons are coupled to any other nuclei, thus enabling the analyst to get an accurate count of the number of carbons in the molecule.

One class of 1-D experiment that is very important is that which gives a count of the number of protons attached to each carbon. The best known of these is called distortionless enhancement by polarization transfer (DEPT). By suitable choice of experimental parameters, the 13C spectra obtained have positive peaks for CH and CH3 groups, negative peaks for CH2 groups, and no signal for quaternary carbons. Varying the parameters allows spectra showing only CH or CH2 or CH3 carbons to be obtained. Thus the number of protons attached to every carbon in the compound being studied can be readily determined.

Although it is more common to obtain high-resolution spectra for protons and carbons, spectra may be obtained for many other nuclei. Those which are most often studied include 15N, 19F, and 31P. Many abused drugs contain nitrogen, however, the low natural abundance and relative insensitivity of the 15N nucleus make it a very difficult atom to study. Comparatively large amounts of material are required in order to obtain spectra in a reasonable period of time. Despite this, a number of reports have been published containing 15N chemical shift data for abused drugs. The other two nuclei (19F and 31P) are essentially 100% abundant and are NMR sensitive but, unfortunately, do not occur in many abused drugs.

### 2.2.1.2 Nuclear Overhauser Effect

When magnetic nuclei are close to each other, there is a dipolar interaction. If the chemical shift of one of these nuclei is irradiated in order to saturate its spin, any nuclei that are close to it may experience a small change in the size of the signal, referred to as the NOE. For small molecules, such as abused drugs, this effect is usually a signal enhancement. The closer the nuclei are to each other, the greater the increase in signal. The maximum amount of enhancement for small molecules is only a few percent of the original size of the signal. Because the strength of the dipolar interaction falls off at a rate which is proportional to the inverse of the distance raised to the sixth power, nuclei must normally be within a distance of about 5 Å in order to see any observable enhancement. In order to observe the small signal enhancements, a difference spectrum must be obtained by subtracting a reference spectrum obtained under “identical” conditions, with the only difference being that the reference spectrum is obtained while irradiating at a blank part of the spectrum instead of at the frequency for the chemical shift for one of the nuclei. When the difference spectrum is plotted, a large negative peak for the irradiated nucleus and small positive peaks for nuclei experiencing an observable NOE are obtained. Thus, this procedure often allows the determination of which protons are close to each other in space, often allowing the analyst to determine the relative stereochemistry in unknown molecules.

### 2.2.1.3 Lanthanide Shift Reagent Studies

The magnetic moments of the unpaired electrons of paramagnetic reagents are capable of producing relatively large chemical shift changes in molecules which are in close proximity.
Most paramagnetic reagents are detrimental to the appearance of NMR spectra because they cause severe line broadening of all the signals. However, a few complexes of the rare-earth elements (lanthanides) do cause substantial chemical shift changes without substantial line broadening on lower field-strength instruments. The most common of these, referred to as lanthanide shift reagents (LSRs), are composed of complexes of europium, praseodymium, or ytterbium with a number of different diketones. The most popular LSRs are complexes with 6,6,7,7,8,8,8-heptfluoro-2,2-dimethylactane-3,5-dione [Eu(fod)₃], Pr(fod)₃, and Yt(fod)₃ or 2,2,6,6-tetramethylheptane-3,5-dione [Eu(dmp)₃], Pr(dmp)₃, and Yt(dmp)₃.

When a shift reagent is added to a solution of the abused drug, it forms a weak bond to the most basic site in the drug, usually a nitrogen or oxygen. The amount of change in the chemical shift is inversely proportional to the distance between the lanthanide atom and the proton (or carbon). The experimental procedure followed in this type of study is to obtain a spectrum of the drug alone and in the presence of varying amounts of the shift reagent. By following the shifting of the different nuclei, one can determine their relative distances from the reagent, thus providing help in assigning the shifts to the appropriate nuclei. In the case of proton studies, the spreading out of the resonance signals may cause the spectrum to be more first-order and thus easier to interpret.

The amount of line broadening experienced by nuclei with a given concentration of LSR is directly proportional to the square of the magnetic field strength. Thus, these reagents are not suitable for use on the more modern high-field spectrometers (>300 MHz). However, on lower-field instruments, they have been used for a wide variety of abused drugs for many years.

### 2.2.1.4 Optical Purity Methods

Another important class of 1-D experiments is that used to determine the optical isomer content of drugs. There are a number of abused drugs for which only one isomer is illicit in many countries. There are three basic types of NMR experiments which may be used to solve this problem. The first method to be developed was the use of chiral lanthanide shift reagents (CLSRs). A related method developed later was the use of CSAs. The final method is the use of chiral derivatizing agents (CDAs).

The use of LSRs was discussed in section 2.2.1.3. There are a number of shift reagents which have optically active ketone groups. Some of the common CSLRs include complexes with the ligands 3-(trifluoroacetyl)-D-camphor [Eu(tfc)₃], 3-(heptafluorobutyryl)-D-camphor [Eu(hfc)₃] and D,D-dicampholymethane [Eu(dcm)₃]. These materials work in basically the same manner as LSRs, but when these compounds are used, they may induce different chemical shift changes for nuclei of optical antipodes. The CLSRs have been used to determine the optical purity of several abused drugs.

An alternative to CLSRs is to use one of a series of compounds referred to as chiral solvents or CSAs. These are optically active compounds possessing an aromatic group and a polar functional group such as an amine, alcohol, or acid. When a suitable CSA is added to a solution of an abused drug which also has a polar group, the CSA forms a weak hydrogen bond with the drug. Because the CSA is optically pure, it forms different complexes with each optical antipode of the drug. Thus, the aromatic-ring current of the CSA is located at different distances from the corresponding nuclei in the drug isomers. This causes the nuclei of the drug to give rise to separate signals for each antipode, thus enabling the determination of the optical purity of the drug. Unlike the CLSRs, there is no line broadening when one uses CSAs, and therefore the higher-field modern spectrometers are the instruments of choice for this type of experiment.

The third method for determining the optical isomer content of abused drugs is the use of CDAs. As with CSAs, the CDAs usually contain an optical center and an aromatic group. They also contain a functional group (such as an acyl chloride) which is capable of reacting and forming a covalent bond with the abused drug. As with the CSAs, the aromatic group is in different proximity to the nuclei of the drug’s antipodes, causing differential shifts for some of the corresponding resonances. In many cases, this difference is sufficient to allow accurate quantification of each isomer. Once again, there is no line broadening like that with CLSRs and the higher-field spectrometers give better separation than the lower-field instruments.

### 2.2.2 Two-dimensional Techniques

2-D techniques in NMR spectroscopy all involve multipulse experiments containing three basic stages, preparation, evolution, and detection. The spectrum that is finally obtained depends on the nature of the preparation and the length of the evolution time. The effects of evolution are not observed directly, but are detected by carrying out a series of experiments in which the evolution time is systematically varied. By following this procedure, one obtains two distinct sets of spectroscopic features, those that influence the magnetization during the evolution time and those that influence the magnetization during the acquisition time. Whereas in 1-D NMR, Fourier transformation converts the time dependence of the magnetization evolution during the acquisition time into frequency data, 2-D NMR uses a second Fourier transformation to convert the time dependence of the evolution time into a second frequency.
2.2.2.1 $^1H\rightarrow^1H$ Correlation Spectroscopy Experiments

There is a class of 2-D experiments which may be performed on any modern high-resolution NMR spectrometer which is referred to as correlation spectroscopy (COSY). One of the most common 2-D experiments is the proton–proton ($^1H\rightarrow^1H$) COSY. The results for this type of experiment are usually displayed as a 2-D contour plot with the 1-D proton spectrum plotted along both the x- and y-axes. The contours in this plot indicate the chemical shifts of the protons that are coupled to each other, as well as for the protons themselves (i.e. diagonal peaks). Figure 1 shows the aliphatic portion of a typical COSY spectrum obtained for 4-propoxy-2,5-dimethoxyamphetamine. Looking under the peak at about 1.85 ppm, it can be seen that there is coupling to protons at 1.05 and 4.10 ppm. These are the signals for the propoxy chain. Similarly, looking under the signal at about 3.70 ppm, coupling to signals at 1.35 and 2.90 ppm can be seen, showing the grouping for the amphetamine alkyl chain. Note that there are no contours under the resonance at 3.90 ppm, other than the one on the diagonal, since there are no protons coupled to the methoxy protons. Thus, to determine which protons are coupled to a particular proton resonance, one simply scans down a column beneath its peak plotted on the x-axis. Contours will be found on rows corresponding to peaks plotted on the y-axis for protons to which it has detectable coupling. By varying the experimental parameters, one can look for either larger short-range or smaller long-range coupling constants. This experiment allows the analyst to determine which protons are separated from each other by two, three, or even four bonds.

2.2.2.2 $^{13}C\rightarrow^{13}C$ Correlation Spectroscopy Experiments

The other homonuclear shift correlation experiment which may be used by the forensic analyst is the $^{13}C\rightarrow^{13}C$ COSY. This technique is often referred to in the literature by its acronym INADEQUATE (incredible natural abundance double quantum transfer experiment). This is a very powerful experiment which allows the determination of all the one-bond carbon–carbon connections in the molecule, enabling the complete skeleton of the compound to be determined, except for those parts joined by heteroatoms. However, because of the extremely low sensitivity of this experiment, and the length of time required to accumulate the data, it is seldom used. Instead, analysts use a combination of other techniques to obtain the same information much more quickly.

2.2.2.3 $^{13}C\rightarrow^1H$ Correlation Spectroscopy Experiments

Because of the importance of determining the connections between hydrogen atoms and carbon atoms, a large number of $^{13}C\rightarrow^1H$ COSY experimental techniques have been developed. In the 2-D contour plots for this type of experiment, the carbon spectrum appears along one axis and the proton spectrum along the other. Parameters may be chosen to emphasize large coupling constants in order to observe one-bond couplings, or to emphasize smaller couplings so that two- and three-bond couplings may be observed as well. In a related experiment, called relayed coherence transfer (RCT), parameters are used which give contours for each carbon atom corresponding to the directly attached protons as well as all the protons coupled to them (i.e. protons on nearby carbons).

2.2.2.4 Nuclear Overhauser Effect Spectroscopy

The 1-D experiment for the NOE was discussed in section 2.2.1.2. There is a corresponding 2-D version of this experiment which goes by the acronym NOESY (nuclear Overhauser effect spectroscopy). Although the $^1H\rightarrow^1H$ version of this experiment is more popular with forensic analysts, the $^{13}C\rightarrow^1H$ version is also available. In the 2-D plot, contours are found for each pair of nuclei which would have produced a medium to strong NOE in the 1-D counterpart. In the 2-D experiment, some weak interactions that are detectable in the 1-D method are sometimes missed. However, one can get most of the results in a single 2-D experiment that would be obtained in many 1-D NOE experiments.
During recent years, advances in NMR technology have led to techniques which provide increased sensitivity over these 2-D methods just discussed. These advances include the introduction of “inverse” or “reverse” detection probes, gradient probes and decouplers which are capable of producing shaped pulses. These exciting advances mean that the forensic analyst can determine the structures of unknown compounds by using ever decreasing amounts of material.

3 APPLICATIONS

3.1 Confirmation of Known Compounds

Although forensic scientists have used NMR for tackling many types of problems, it is most often used in the study of abused drugs. While it is true that the majority of illicit drugs may be conveniently analyzed by other methods such as infrared (IR) and mass spectra, NMR is still used in a number of forensic laboratories. Some drugs that possess hygroscopic or polymorphic properties are difficult to analyze by IR. Also, many drugs fragment in such a manner that their mass spectra are ambiguous and difficult to interpret, especially in cases where there may be a number of closely related isomers. NMR provides an attractive alternative approach for these types of drugs since it is not affected by such problems and is a very powerful method for distinguishing between isomers.

3.2 Identification of Unknown Compounds

NMR spectroscopy provides the forensic analyst with one of the most powerful techniques for the identification of unknown compounds. For laboratories which have modern spectrometers, the full range of experiments described in section 2.2 are available. While IR and MS are useful for identification of known compounds, especially by means of their library search capabilities, NMR is usually the key spectroscopic technique for identifying true unknowns. For new abused substances such as “designer drugs”, NMR proves to be invaluable in the determination of their structures. The term “designer drug” refers to compounds, related to abused drugs, which have been synthesized to circumvent legislation in the country of sale. These materials are usually a modified illicit drug in which a substitute has been added or changed (substituting an ethyl for a methyl, for example). Examples of these were reported in Canada and the USA during the late 1980s and early 1990s for fentanyls, amphetamines, synthetic opiates, and phencyclidines.

The exact series of NMR experiments used to solve unknown structures may vary somewhat, depending on the preferences of the particular spectroscopist. However, the general procedure will be the same. The analyst will carry out the following series of experiments until enough information has been obtained to identify the unknown, or until enough information is obtained for the investigator to be able to determine which specialized experiment is required to complete the study.

First, the abused drug sample is prepared for study as described in section 2.1. Then the spectroscopist obtains a high-resolution $^1$H-NMR spectrum using an appropriate deuterated NMR solvent. Careful inspection of this spectrum gives a great deal of structural information. Chemical shifts and integration reveal the relative number of protons in each area (aliphatic, olefinic, aromatic) and the coupling patterns reveal information on the proximity of many protons. Next, $^{13}$C-NMR and DEPT spectra are obtained to determine the number of different carbons and the numbers of protons attached to each. Chemical shifts of the carbons give important information about each carbon’s environment. Often, the combination of proton and carbon data is enough to solve the structure of the unknown. If it is not, 2-D spectra and NOE experiments are used to establish connectivity and proximity of the nuclei in the molecule. The information obtained is sufficient to establish the skeleton of the molecule. Sometimes, especially when there are NMR-“silent” nuclei (such as chlorine, bromine, oxygen, nitrogen) present, it may be necessary to obtain MS and/or IR data in order to complete the structure. While it is true that spectra can be obtained for most of the “silent” nuclei, it is usually much quicker and easier to use other spectroscopic techniques to establish their presence.

3.3 Quantification

After the abused drug in a police exhibit has been identified, it is sometimes necessary for the analyst to provide quantitative results. In many seizures, the drug is found to be “cut” with other compounds ranging from sugars or starch to other drugs. Cocaine is one drug that is frequently cut with cheaper, more readily available drugs such as lidocaine. NMR provides a quick, accurate, and reliable method for quantifying abused drugs in most seizures. Depending on the complexity of the mixture, the analyst may use either proton or carbon spectral analyses. If absolute quantification is required, an accurately known amount of a suitable standard (see section 2.1) must be added to the sample before the analysis. If only relative quantities of substances present are required, there is no need for an internal standard. For relatively simple mixtures, proton NMR, because of the shorter relaxation times and higher sensitivity when compared with $^{13}$C-NMR, is often the method of choice. However, for more
complex mixtures, $^{13}$C-NMR may prove to be the better option. Although NMR is well suited for quantification of abused drugs, relatively few publications have appeared in this area. In part this is due to the fact that this method is so routine as to not warrant publishing the results.

3.4 Impurity Profiling

When a $^1$H-NMR spectrum of an exhibit is recorded, signals are obtained for the protons of the impurities as well as for the abused drug itself. Careful examination of these “extra” peaks will often allow the identification of one or more impurities. Integration, or comparison of relative peak heights, will usually give a very good estimate of the percentage of each impurity present. In cases where the impurity(ies) cannot be identified in the presence of the drug, it is often possible to separate it (them) from the drug by methods discussed in section 2.1. Once the drug resonances no longer mask the impurity peaks, it is much easier to perform the required NMR techniques for the identification of this material.

Identification and quantification of the impurities in drugs is often helpful in police intelligence operations. Knowledge of the impurities in exhibits (including any solvent residues) can often give the analyst information concerning the synthetic route used to prepare the drug and solvents used in their cleanup/purification. Comparison of results for different seizures may then be used to determine if they are likely to be from the same source.

3.5 Optical Purity

There are a number of drugs for which only certain optical isomers are illegal. This differs from country to country. For example, methamphetamine is an illicit substance in Canada, whereas in the USA only the (+)-isomer is controlled. Levomethorphan is an internationally recognized narcotic, but its optical isomer, dextromethorphan, is a common ingredient in over-the-counter cough medications. Dextropropoxyphene is internationally recognized as a narcotic, while levopropoxyphene, which is used as an antitussive, is not. By using the methods described in section 2.2.1.4 NMR may quickly allow the determination of the optical purity of these types of drugs.

The study of optical purity in abused drugs is not limited to those drugs for which there is legislation against specific isomers. There are a number of abused drugs whose precursors are available in either racemic or optically pure form. Determining the optical content of the abused drug will sometimes allow the forensic analyst to determine the starting material and/or give evidence as to the synthetic route.

3.6 Analysis of Body Fluids

Modern forensic laboratories must often investigate the involvement of abused drugs in traffic accidents, murder, sexual assault, and other crimes. In many of these cases, the analysts will analyze samples of body fluids or tissues in attempts to measure levels of abused drugs. The concentration of drugs in the blood varies over a wide range, from tens of milligrams per milliliter for ethanol, to nanograms per milliliter for most drugs and their metabolites. However, in some extreme cases of overdoses, drug levels of 100 micrograms per milliliter are observed. The lower range of these drug and metabolite levels is beyond the sensitivity of NMR, but the higher end values are not. Detection limits for $^1$H-NMR are in the low microgram per milliliter range on newer high-field spectrometers. It has proven difficult to obtain any lower limits due to the background signals from endogenous compounds in the blood and urine samples. The fluorine signals of fluorinated steroids are detectable at submicrogram per milliliter levels because there is no background. For nonfluorinated abused drugs, analysts have the option of performing sample work-up procedures such as solid-phase extraction or preparative HPLC cleanup before analysis. This also allows the analyst the opportunity to concentrate the drug or metabolite from several milliliters, down to the volume ($<0.5$ ml) required for NMR analysis, thus bringing many more samples into the range of levels detectable by NMR.

4 COMPARISON WITH OTHER FORENSIC TECHNIQUES

4.1 Advantages

NMR will detect all soluble organic compounds present in the sample. Other techniques, such as HPLC or MS, will often not detect impurities. For example, these techniques will not observe any compounds that either elute in the solvent front or do not come off the column at all under the conditions used. Careful examination of the impurity peaks in the NMR will often give significant clues as to their identity and allow quantitative estimates as to the amounts present. HPLC provides little information about the identity of unknown impurities and is not reliable for quantifying them since it does not give equimolar responses for different materials. In fact, compounds with low or no ultraviolet (UV) absorbance may not be detected, even when present at significant levels.

NMR is a nondestructive technique. As long as the sample material is stable in the solvent chosen for the study, the entire sample may be recovered and then
used for other studies. Hence, because a sample is not recoverable when techniques such as HPLC and IR are used, NMR studies should be performed before these other techniques whenever there is a limited amount of sample.

NMR spectroscopy provides the most powerful structure elucidation technique available to the forensic analyst for unknown materials. One area where NMR outshines other spectroscopic techniques is in the determination of isomers. Its true value comes from its ability to establish the proximity of nuclei in a molecule by using coupling constants (through one, two, or three bonds) or with NOE measurements (to within approximately 5 Å for nuclei). The NMR chemical shifts and coupling constants easily allow the discrimination of geometric or positional isomers, even when there are no authentic materials for comparison purposes. It would be much more difficult, if not impossible, to obtain this information using spectroscopic techniques such as IR or MS (without reference standards).

The most common method by which analysts determine the optical purity of drugs has been by either specific optical rotation or HPLC, using a chiral column or a chiral derivatization procedure. However, NMR has a number of advantages over optical rotation and HPLC in studies aimed at determining enantiomeric composition of any organic compound, including abused drugs. This is especially true if methods are required which are capable of determining optical antipodes at levels of less than a few percent. This can be important for police intelligence work where the starting materials for the abused drug may contain small amounts of its enantiomer. Establishing that the abused drug has the same optical content as the potential starting material gives good evidence of the synthetic route used. Using modern spectrometers and the techniques described above, it is usually possible to develop methods that can quantify the abused drug’s enantiomer at or below levels of 0.1%. Some of the advantages of NMR would include the following.

- **NMR results are accurate and precise, even when the substance of interest is present only at lower percentages.** Optical rotation cannot be used to determine low levels of impurity, especially in drugs with a low specific optical rotation.
- **The time required for analysis is usually less for NMR than for HPLC.** This is especially true if there is no existing method, since it is usually quicker to develop an NMR method than an HPLC method. If a method already exists it is still much faster to obtain the results by NMR. For NMR, the procedure would normally involve simply dissolving the drug in an appropriate solvent, adding the calculated amount of CSA, acquiring the proton spectrum, and measuring the appropriate peaks in the spectrum. This may normally be done within half an hour. For HPLC, one must set up the LC system (put in the most suitable column for the analysis, prepare the mobile phase), check the performance of the column by running a standard, and then run the sample. All this requires much more than half an hour.

- **NMR methods are more “robust” than HPLC methods.** Once a method has been developed for NMR, it should work on any spectrometer of equal field strength (or higher field strength for CSAs and CDAs). Because of variability of columns, HPLC methods have to be checked and sometimes modified when changing columns.
- **NMR provides “bonus” information.** Since NMR detects all signals for the nucleus under study, it will detect not only the abused drug (and its enantiomer), but also any impurities present.

### 4.2 Disadvantages

One of the main criticisms of NMR as an analytical technique is its relative insensitivity when compared to other methods such as MS or HPLC. While these other instruments may require only nanograms or less of the sample, NMR usually needs micrograms or more. While this limitation is of little concern for drug seizures of one or more doses of the abused substances, it does limit its use in analyses of body fluids for drugs and their metabolites.

Another common complaint about NMR is the cost of the instrumentation. While it is true that the highest-field-strength spectrometers are very expensive (millions of dollars each), the models that have been around for several years (currently field strengths of 200 to 600 MHz) tend to be comparable in cost to mass spectrometers. In general, NMR spectrometers have proven to be very reliable instruments, with relatively low repair and maintenance costs. Thus, if one considers the cost per year, NMR spectrometers may not be as bad as is generally thought.

Another concern often brought up when discussing the use of NMR is the need for highly specialized expertise in the area. While it is true that considerable expertise is required in order to take full advantage of the full capabilities of modern spectrometers, very little knowledge is needed to use NMR results for more routine purposes. Thus, for positive identification of known compounds, simple comparison of spectra with those of authentic materials is all that is required. This is very similar to the use of IR “fingerprinting” to identify compounds. It is also possible to automate the identification by use of library searches of NMR databases, comparable to those for IR or MS.
5 SURVEY OF THE LITERATURE

Abused drugs may be described as belonging to either of two categories, (1) fully synthetic (e.g. amphetamines, Phencyclidine; 1-(1-phenylcyclohexyl)piperidine (PCPs)); and (2) natural source or semisynthetic modifications (e.g. cocaine, heroin). NMR spectra and spectral data have been reported for most abused drugs. There are a number of books which contain spectral data for drugs and related compounds. One set of books of particular interest to forensic analysts is the excellent collection of instrumental data, including 300 MHz proton NMR, MS, IR and UV spectra, found in Mills and Roberson. There have also been two recent reviews of the uses of NMR in forensic science.

5.1 Amphetamines and Related Substances

Amphetamine (1) belongs to a class of compounds referred to as phenethylamines. Abuse of these compounds began to increase progressively in the 1960s. Their effects range from aggression and psychosis to hallucination and distorted perception. Amphetamine and its analog, methamphetamine (2), have medical uses and are legitimately manufactured. Clandestine laboratories produce these materials, as well as many substituted analogs, using a variety of synthetic routes. Although many possible synthetic routes for the production of amphetamines are described in the literature, only four are generally used in clandestine laboratories. These are the Leuckart synthesis, reductive amination, or reduction of the appropriate oxime or nitrostyrene. An examination of the impurities and optical state of the resulting materials is often useful in police intelligence work.

\[
\begin{align*}
\text{(1)} & \quad \text{CH}_2\text{CH}_2\text{NH}_2 \\
\text{(2)} & \quad \text{CH}_2\text{CH}\text{NHCH}_3
\end{align*}
\]

The large number of substituted amphetamines and methamphetamines has required the development of analytical techniques capable of identifying these closely related compounds. Consider, for example, the simple case of ethoxydimethoxyamphetamine (analogs of trimethoxyamphetamine, with one methoxy being replaced by an ethoxy). There are 16 possible isomers, which may be split into three groups, those with the two aromatic protons ortho to each other (six isomers, Figure 2a), those with the aromatic protons meta to each other (seven isomers, Figure 2b) and those with the aromatic protons para to each other (three isomers, Figure 2c). The proton NMR spectra for each of these compounds would be expected to be distinct. Even without standards, it is not difficult to determine which isomer is present if NMR is used. First, an examination of the coupling constants for the signals for the aromatic protons reveals immediately to which of the three groups of isomers the compound belongs, since ortho couplings are ~8 Hz, meta couplings are ~2 Hz and para couplings are usually not resolvable (~0 Hz). Performing a few NOE experiments will then allow the determination of which substituents are adjacent to each other, thus completing the structure determination.

Figure 2 The 16 possible isomers for ethoxydimethoxyamphetamine divided into three groups: (a) those with the aromatic protons ortho to each other; (b) those with the aromatic protons meta to each other; (c) those with the aromatic protons para to each other. (A = amphetamine side chain (CH$_2$CH(NH$_2$)CH$_3$); E = ethoxy (OCH$_2$CH$_3$); M = methoxy (OCH$_3$)).
Most of the abused drugs in this class are synthetic in origin. There are a few exceptions. The hallucinogen mescaline, from the peyotyl cactus, *Lophophora williamsii* or *Anhalonium lewini*, was popular in the 1960s. More recently, another natural product, khat, *Catha edulis*, has shown up in a number of countries. Khat is a small tree or shrub that is native to east Africa and southern Arabia. Its leaves are used for chewing to get an amphetamine-like stimulation. The principal active components in khat are cathinone (3) and cathine (4). Study of the alkaloid content, including optical isomers, by NMR methods can be used to provide police with information about the origin of the material.

5.2 Phencyclidine and Related Substances

PCP (5) was first marketed as an anesthetic in 1958, but was withdrawn in 1967 because of adverse effects. Despite its neurotoxic effects, it became a drug of abuse because of its hallucinogenic and stimulant effects. A large number of analogs have also appeared as “street drugs” or “designer drugs”. The PCPs produced in clandestine laboratories are known to often be impure, sometimes containing the toxic intermediate 1-piperidinocyclohexanecarbonitrile (PCC) (6). As with the amphetamine designer drugs, unknown new PCP analogs are usually most easily identified by means of NMR spectroscopy. Figure 4 shows the spectra of two PCP analogs and illustrates the ease with which they may be identified from simple proton NMR spectra. MS may be used to determine that the molecular weight of these compounds is 14 higher than that of PCP, indicating a possible methylation product, but without authentic standards the isomers may not be easily determined. Examination of the spectrum in Figure 4(a) reveals a singlet at about 2.4 ppm which integrates to three protons. This indicates that the compound probably contains a methyl on the aromatic ring. The appearance of the aromatic proton resonances indicates para substitution, showing that the methyl is in the 4 position. The spectrum of the other isomer shown...
used as a surgical anesthetic. This drug and many related compounds have activities which make them more than 100 times more potent than morphine. Because of this, more than 100 deaths have been attributed to overdose from these compounds. One of the first analogs to appear on the streets was referred to as “China White” or “synthetic heroin”. Its identity was determined as α-methylfentanyl (8) by using a combination of MS and 1H-NMR. A large number of designer drugs of this class appeared in the early 1980s and clandestine laboratories continue to be found, especially in the USA.

5.4 Opiate Alkaloids

Opium is derived from the opium poppy (Papaver somniferum) or other poppy species which may be grown in many countries. Untreated opium contains a mixture of about 30 alkaloids. Morphine (9) is the principal opium alkaloid, with some of the other common alkaloids being codeine (10), thebaine (11), papaverine (12), and noscapine (13). Heroin (14), the main opiate-derived abused drug, is produced by the simple diacetylation

---

**Figure 4** Proton spectra of two PCP analogs: (a) the 4-methyl derivative; (b) the benzyl derivative.

In Figure 4(b) contains a singlet at about 3.2 ppm which integrates to two protons. The aromatic ring resonances integrate to five protons. Combining this information reveals that this isomer is the benzyl derivative, rather than another aromatic methylated isomer.

5.3 Fentanyls

The abuse of fentanyl (N-(1-phenethyl-4-piperidyl)propionanilide) (7) and its related compounds began in the USA in 1979. Fentanyl is a narcotic analgesic widely

of morphine. All these related compounds may be readily identified by their distinctive NMR spectra. Also, the impurity profiles for these compounds may be very useful in police intelligence work, as discussed above. Illicit heroin samples are usually cut with a range of other substances, such as caffeine, diazepam, and methaqualone. It has been found that the street samples of heroin generally average a purity of less than 40%. Identification of the other materials may allow law enforcement agencies to link seizures from different sources.

5.5 Cocaine and Related Substances

Cocaine (15), the first local anesthetic to be discovered, is a strong central nervous system stimulant whose abuse has grown greatly in the last two decades in many parts of the world. Cocaine is a tropane alkaloid, as are atropine and scopolamine, both of which have valuable medical uses. Although cocaine has been synthesized, and there have been reports of a few clandestine laboratories producing it, cocaine is obtained primarily from the leaves of the shrubs *Erythroxylum coca* or *Erythroxylum novogranatense*, which are cultivated in South America. The leaves are extracted in clandestine laboratories close to the growing regions. Once again the impurities (including the other minor alkaloids) give valuable intelligence information to the law enforcement agencies. As with the other drugs discussed, NMR provides a quick and accurate method for easily distinguishing between cocaine and all the other closely related alkaloid compounds. Since cocaine is rapidly metabolized, only metabolites are seen in body fluids. These include benzoylecgonine and ecgonine methyl ester. If alcohol drinking is combined with cocaine abuse, benzoylecgonine ethyl ester is formed in the body. All these compounds have been studied and fully characterized by NMR spectroscopy.

![Cocaine](15)

5.6 Cannabinoids

Cannabis is the name given to material prepared from the *Cannabis sativa* plant. The preparation occurs as herbal cannabis (marijuana, the flowering or fruiting part of the plant) or cannabis resin (an amorphous semi-solid exuded by the flowering tops). Cannabis is a mixture of more than 60 compounds, the cannabinoids. It is a mild hallucinogen, which induces light-headed euphoric intoxication. The primary active substance in cannabis is Δ⁹-tetrahydrocannabinol (16), which was identified by use of ¹H-NMR. Since the mid-1960s, more than 100 other cannabis substances have been identified, with ¹H-NMR playing a major role in the elucidation of their structures. NMR has also been used in the identification of a number of related semisynthetic drugs. Although NMR is not appropriate for the routine analyses of cannabis products, it is used for the authentication of pure substances to be used by other methods and for the identification of new related unknown compounds.

![Cannabis](16)

5.7 Ergot Alkaloids

Ergot is a dried material from the fungus *Claviceps purpurea*, which grows on rye and other grains. Ergot alkaloids have also been found in many plant species, such as the *Convolvulaceae* (morning glories). Ergot material yields four main classes of alkaloids: lysergic acids, lysergic amides, clavine, and ergot peptides. The most common drug of abuse derived from ergot is LSD (or lysergide) (17), which is produced by the amination of lysergic acid. The abuse of LSD began in the 1960s. Currently, LSD is encountered as either microdots (small tablets), or, more commonly, as impregnated paper or card squares in one of more than 200 printed designs reported so far.

![Ergot Alkaloids](17)

LSD is a very potent hallucinogen, with street samples normally containing between 25 and 100µg per dose. Since LSD is unstable in the presence of light or high temperatures and moisture, the forensic analyses present some difficulty. Gas chromatography (GC) analysis requires conditions that are highly specific for this drug. Thus either HPLC or ¹H-NMR is more useful. Even with the lowest amount which will give a perceptible effect (~10µg), it is feasible to use modern high-field
s Spectrometers (≥400 MHz) to obtain proton spectra in a reasonable amount of time.

As discussed above, it is very important to know the identity of a substance when working in the judicial system. It is crucial to be able to distinguish between isomers of compounds, especially if one of them may be an illicit material while the other may be a legal substance. In the early 1980s in the USA, it was realized that existing chromatographic methods for LSD were not adequate for distinguishing this abused drug from the noncontrolled isomer, lysergic acid methylpropylamide (LAMPA). It is no problem to distinguish LSD and LAMPA (or the methylisopropyl isomer) by simple 1H-NMR. Chromatographic and MS methods have also been developed for differentiating LSD and LAMPA.

5.8 Quinazolinones

There are a number of abused drugs which belong to the quinazolinone category. The two most often encountered in forensic analysis are methaqualone (18) and mecloqualone (19). Both are hypnotics, manufactured as proprietary pharmaceuticals. Illicit samples may arise either by diversion of prescription tablets or from clandestine laboratories. Methaqualone is one of the substances which is sometimes used as a diluent for heroin samples. NMR spectra for these compounds are readily available in the open literature.

There has been one report\(^4\) of a “designer” methaqualone. Spectroscopic evidence indicated that it was a methylated analog. The problem was to determine the position of the methyl group. It was known to be one of the four isomers with the methyl on the phenyl ring. The coupling pattern indicated that the methyl was in either the 4 or 5 position. NOESY correlations were then used to show definitively that the compound was 2-methyl-3-(2,4-dimethylphenyl)-4(3H)-quinazolinone (20) rather than the 2,5-dimethyl isomer. The structure was confirmed by synthesis. The authors discussed the improved efficiency of using NMR as a means of eliminating the need for synthesis of all the other possible isomers.

5.9 Barbiturates

Some of the earliest forensic NMR work was done on barbiturates. These studies showed that NMR provided an excellent method for identifying these compounds, even in mixtures which were difficult to analyze by other methods, without the need for prior separation. There are a number of papers, including one by Wilson et al.\(^5\) (which contains spectra of all barbiturates and their salts that are under international control), which may be used to provide the forensic analyst with all the spectral data necessary to identify any abused drugs in this class.

5.10 Benzodiazepines

In most countries, benzodiazepines have, to a large extent, replaced barbiturates as the sedative or tranquilizer of choice by drug users. There have been reports of the use of these medications as “club” or “date rape” drugs. Wilson and Avdovich\(^6\) have shown that 1H-NMR may be used for the identification, differentiation, and analysis of these drugs and presented a complete collection of 80 MHz spectra for all 33 benzodiazepines under international control.

5.11 Other Abused Drugs

NMR spectra and/or spectral data have been reported for most abused drugs that do not fall into one of the classes discussed above. In most cases, although the data were not reported in the context of forensic analysis, they may still be used for such purposes.

Extensive amounts of 1H- and 13C-NMR data have been published for steroids, including anabolic steroids which have been a problem in sports regulation for many years. Currently, GC/MS is the most important technique for the forensic detection of steroids and their metabolites. There have been very few reports of the use of NMR in forensic analysis of steroids. However, NMR should not be overlooked as a quick method of identification of (purified) steroids when GC/MS is not appropriate. An important advantage of NMR over other techniques is its inherent ability to identify “designer” modifications in drugs such as steroids.

6 CONCLUSIONS

NMR has played an important role in the forensic analysis of drugs of abuse for many years. Although it has not been used as the method of choice for routine analyses, the advent of NMR spectrometer accessories for automated data collection and analysis may change this situation in the near future. There is no doubt that NMR will continue...
to play a vital role in the identification of unknown compounds such as “designer drugs”.

This article summarizes the theory behind the uses of DNA analysis for identification purposes. Various techniques are summarized and their strengths and weaknesses are contrasted. The theoretical basis of the polymerase chain reaction (PCR) and various types of PCR reactions are introduced. A table is provided with loci that can be used for the forensic analysis of DNA. The availability of kits is summarized. Finally, a discussion of mitochondrial DNA analysis is performed.

1 INTRODUCTION

1.1 The Human Genome

The human genome consists of approximately $3 \times 10^9$ basepairs (bp) of DNA arranged on 46 chromosomes. An individual gene or location on a chromosome is called a locus. There are 44 autosomes (numbered 1–22) and two sex chromosomes (X or Y) in each individual. There are two homologous autosomes, one inherited from the mother and one inherited from the father. Females inherit an X chromosome from both parents and males inherit an X from their mother and a Y from the father. Thus, every individual has two copies of every autosomal gene. Each copy of a gene is called an allele. When the paternal and maternal alleles are identical, an individual is homozygous at that locus, and when the paternal and maternal alleles are different, an individual is heterozygous at that locus.

1.2 Hypervariable Regions

In the human genome there are noncoding regions that consist of stretches of repeating sequences of DNA. The sequences can vary in size from 2 bp (dinucleotide repeats) to more than 50 bp repeated for several iterations. The number of these repeated sequences present on any individual’s chromosomes differs from chromosome to chromosome and from individual to individual. Repeated fragments of 350–1000 bp are generally referred to as amplified fragment length polymorphisms (AmpFLPs) and shorter fragment sizes in the range 100–300 bp are called short tandem repeats (STRs).

There are other areas of variability, the most important of which are the human lymphocyte A (HLA) histocompatibility loci. Analysis of the protein polymorphisms in the HLA loci has long been a cornerstone of serological paternity testing. PCR-based HLA typing is also possible and is the basis of commercially available kits.

1.3 History of DNA Forensic Analysis

Initially DNA forensic testing relied on one of two seminal techniques: Southern blot analysis of regions with a variable number of tandem repeats (VNTR) (single locus gene testing); and a technique developed by Dr Alec Jeffries, which used probes that recognize a number of loci in the genome, called multilocus DNA testing (popularly known as DNA fingerprinting).

It is important to note that DNA fingerprinting is a patented technology of Cellmark Diagnostics and should not be used to describe any other type of DNA test. Both of these techniques have largely been supplanted by PCR technologies. PCR is a technique...
that amplifies a particular sequence of DNA and allows the analysis of any known DNA sequence by amplifying the sequence of interest approximately a million times. Once the PCR product is obtained, analysis can be performed by a wide variety of techniques that include size fractionation, hybridization, DNA sequencing and various microchip technologies (see below).

1.4 Comparison of Polymerase Chain Reaction to Other Techniques

The advantages of PCR over prior technologies are that PCR requires much less DNA (even a single human cell can be genotyped reliably) and is successful on partially degraded or damaged DNA, technical aspects are simple and allow automation, analysis does not require radioactivity, and the analysis can be accomplished in a matter of hours rather than days for Southern blot technologies. In addition, the fragment sizes are discrete, allowing for easy comparison among laboratories and standardization for the purposes of offender databases. The disadvantages of PCR are that the polymorphic loci tend to be less variable, so a larger number of loci are required to achieve equivalent statistical significance, and because PCR is capable of amplifying minute amounts of DNA, contamination by extraneous DNA sequences at crime scenes or forensic laboratories is a much more significant problem in PCR than in standard DNA techniques.

2 DESCRIPTION OF TECHNIQUE

2.1 Description of Various Forms of Polymerase Chain Reaction

PCR uses a thermally stable DNA polymerase and two or more synthetic oligonucleotides that are usually 16–25 bp in length. For forensic analysis the primers are designed to frame a hypervariable region of DNA. In simple PCR two primers are used: an upstream primer on the 5′ end of the locus of interest and a downstream primer on the 3′ end. The two primers must be complementary to opposite strands of the DNA (see Figures 1 and 2). In nested PCR, two sequential PCR reactions are performed. The first reaction uses two outside primers (see Figure 2) and 20–30 cycles of PCR are performed. Following this first round of PCR, a small aliquot of the initial PCR mixture is added to a new tube with PCR buffer and two inside primers. Then a second round of PCR is performed. Nested PCR was developed to genotype reliably single cells and is sometimes able to amplify minute quantities of DNA when standard PCR fails. In hemi-nested PCR one of the primers added to the second round is the same as one of the primers used in the first round of PCR.

2.2 Polymerase Chain Reaction Primers

Primers are usually 16–30 bp in length and can be synthesized on commercially available oligonucleotide synthesizers or ordered from a number of commercial laboratories. Oligonucleotide synthesizers use phosphoramidite chemical synthesis, with the first nucleotide linked to a
After 20 rounds of PCR ~ 1 million copies

After 30 rounds of PCR ~ 1 billion copies

Figure 2 Schematic of PCR reaction.

solid support. Then successive nucleotides are added in a 3′–5′ direction by automated phosphoramidite synthetic steps. Following the synthesis, the oligo is removed from the column. The final nucleotide is protected with a trityl group. Synthesizers can be programmed to leave the final trityl group “on” (trityl-on synthesis) or to cleave the final group (trityl-off synthesis). In trityl-on synthesis all oligonucleotides containing less than the full-size product will not have a trityl group at the 5′-end, because the first step in the subsequent round of synthesis de-protects the last nucleotide. Therefore, a purification step that separates all trityl-containing nucleotides from nontrityl-containing nucleotides will assure that only full-length oligonucleotides are present. However, for most forensic purposes, primers synthesized trityl-off are equally efficacious.

2.3 DNA Preparation

There are several methods to prepare DNA for PCR reactions. These include proteinase K digestion with or without organic extraction, organic extraction only, chelex, alkaline lysis buffer, and simply dissolving the specimen in PCR buffer. DNA preparation from vaginal or anal swabs in rape cases can be subjected to differential lysis procedures. In this procedure, a gentle lysis is performed using detergent and proteinase K to lyse vaginal epithelial cells, leaving the sperm intact. The two fractions are separated and the sperm are lysed by the addition of ethylenediaminetetraacetic acid (EDTA) or dithiothreitol (DTT) to the lysis mixture. Successful PCR analysis has been made from licked stamps, saliva on skin, cigarette butts, fingerprints, hair roots, tooth pulp, paraffin-embedded tissue sections, and histology slides, in addition to the standard tissues of blood and cheek swabs. (6–40)

2.4 Preparation of Polymerase Chain Reaction Mixture

Once the DNA has been prepared, the PCR mixture is prepared. In simple PCR, one set of two primers is added, along with sufficient quantities of the four deoxyribonucleotide triphosphates (dNTPs), a thermally stable DNA polymerase, in the appropriate salt and pH for the particular polymerase and primer set. The reaction mixture is then placed in a thermocycler (PCR machine). Thermocyclers are programmable instruments that perform repeated cycles of heating and cooling of samples for PCR. (41–43)

2.5 Model Polymerase Chain Reaction Cycle

For most applications, “Hot Start” PCR is the preferred method. If all the reagents are present in the PCR reaction when it is placed into the thermocycler, nonspecific primer binding to DNA can occur as the temperature begins to increase from room temperature to the initial melting temperature. As soon as the priming occurs, the polymerase can begin chain elongation, thus creating a nonspecific PCR product that participates in subsequent cycles and can interfere with interpretation of the PCR reaction. In Hot Start PCR, one or more critical reagents are left out of the PCR mixture (dNTPs or polymerase) and not added until after the initial melting step while the reaction mixture is held at the elongation temperature. A typical PCR cycle would be as follows:

95 °C for 10 min (melting of DNA performed only once)
72 °C until final reagent is added (for Hot Start)

Begin performing the following cycle
65 °C for 2 min (reannealing)
72 °C for 2 min (elongation)
95 °C for 2 min (melting)

Cycle for 18–40 cycles
72 °C for 10–20 min (final chain elongation, performed only once)
4 °C indefinitely

2.6 Complexity of Polymerase Chain Reactions

PCR reactions can be separated according to the complexity of analysis, as follows:

- Standard PCR – one set of two primers, one PCR reaction, one locus analyzed
- Fully nested PCR – two sets of primers, two PCR reactions, one locus analyzed
- Hemi-nested PCR – two sets of primers, but one outside primer is shared by both reactions
- Multiplex PCR – two or more sets of primers, one PCR reaction, two or more loci analyzed
- Nested multiplex PCR – several reactions, 2^n sets of primers (n = number of cycles)

2.7 Exponentiality of Reaction

The mechanism of the PCR reaction is shown in Figure 2. Theoretically, the reaction is exponential, with \(2^n\) copies made.

3 ANALYSIS OF POLYMERASE CHAIN REACTION PRODUCTS

3.1 Manual Techniques

Once the PCR reaction has been completed, the products can be analyzed in a number of ways. The most common AmpFLP and STR analytical method is gel electrophoresis with ethidium bromide staining. Ethidium bromide is a dye that intercalates into the DNA helix between bases. When exposed to ultraviolet light, the ethidium-bromide-stained DNA fluoresces, allowing a photograph to be taken. Silver stain has also been used to visualize PCR products. (44–53)

3.2 Automated Techniques

Newer methodologies utilize fluorescent PCR primers. This allows detection of PCR fragments on automated DNA sequencers. In the sequencer detection, the PCR products are separated on either denaturing acrylamide gels or by capillary electrophoresis. The fragments are detected by a laser fluorescence detector (or detectors). Some instruments have the capability of analyzing four different colors. If one designs the primer systems correctly so that ranges of the fragment lengths differ for each system without overlap, it is possible to analyze several different systems using the same color. Then, combining such a system with the capability of using three different colors allows a simultaneous assay of more than 20 systems. (44–53)

4.3 Mitochondrial DNA Testing

PCR can also be used to analyze mitochondrial DNA. Mitochondrial DNA analysis has two advantages over standard PCR analysis. Because mitochondrial DNA is inherited completely from the mother, mitochondrial DNA analysis allows easier identification of unknown individuals from mass graves and mass disasters. In standard STR or AmpFLP analysis, reverse paternity testing must be performed. In order to accomplish this, samples from both parents are required for analysis. In cases of genocide and war crimes, this is rarely possible. In addition, any relative related through the mother can be used as a source of DNA for mitochondrial DNA identification. Another advantage is that mitochondrial DNA is present in hundreds to thousands of copies per cell, in contrast to genomic DNA that is present in only one copy per cell. Therefore, some samples that have insufficient DNA for standard PCR or nested PCR analysis may yield results with mitochondrial DNA amplification. However, mitochondrial DNA analysis has drawbacks compared to standard analysis for identity testing. In general, mitochondrial DNA is much less polymorphic than the STR or AmpFLP loci, so that in the event of a nonexclusion, the statistical power of the conclusions is not as significant. (163–169)

Pyrolysis Gas Chromatography in Forensic Science

Robert D. Blackledge
Navy Criminal Investigative Service, Regional Forensic Laboratory, San Diego, USA

1 INTRODUCTION

PY/GC is the breakdown of organic molecules by the application of heat in the absence of oxygen and the separation and detection of the pyrolysis products by GC. PY/GC is most often used in forensic science to help answer the question: “Could samples A and B have originated from a common source?” A “yes” answer may help to provide an association between a suspect and the crime. PY/GC is a destructive technique and forensic science samples are often quite limited. However, a sample size of a few micrograms down to even tenths of a microgram is all that is required. If a flame ionization detector (or other standard GC detector) is used to identify the elution of the pyrolysis products, the comparison of samples A and B is based on pattern matching (retention times and relative peak heights). If the GC is equipped with a mass selective detector (MSD), a positive comparison is strengthened since it may be possible to identify the various peaks based on their mass spectra.

2 PYROLYSIS METHODS

To be of forensic science value the pyrolysis must be performed in a reproducible manner. PY/GC will then produce pyrolysis chromatograms (known as pyrograms) that serve as identifying “fingerprints”. Resistive heating, Curie point (inductive heating) and microfurnace are the three most common pyrolysis methods, and commercial instrumentation is available for each.

2.1 Resistive Heating

In the most popular pyrolysis system based on resistive heating a self-sensing resistively heated platinum wire coil or ribbon is used to heat the sample rapidly. In the coil probe the sample may be placed either in a quartz boat or inside a quartz tube, which is then inserted into the middle of the coil. In the ribbon probe (Figure 1) the sample (which is usually a high boiling liquid or a solid dissolved in a volatile solvent) is applied directly to the ribbon. The liquid should flow along the ribbon leaving a relatively uniform thin coating. The sample-containing resistive heating unit (probe) may be either placed in a separate unit having a heated transfer line interfaced to the GC injection port. In either case, upon pyrolysis the carrier gas sweeps the vapors into the GC column. An electrical cord extends from the probe to a control unit which controls the heating modes (pulse or programmed) and the pyrolysis temperature and duration. Pyrolysis temperatures may be selected in 1 °C increments up to 1400 °C. Figure 3 shows the results from the successive pyrolysis of a polystyrene sample and is indicative of the potential reproducibility of the method.
2.2 Curie Point (Inductive Heating)

In Curie point pyrolysis the sample is on or contained within a ferromagnetic wire or foil. The foil is within a radiofrequency field (RFF). By induction heating the RFF heats the foil, whose temperature rises until it reaches its Curie point, the temperature at which it changes from ferromagnetic to paramagnetic. At the Curie point the temperature remains constant. Thus Curie point pyrolysis affords a very reproducible temperature rise time and final temperature (Figure 4). Because the Curie point varies according to the ratio of ferromagnetic metals (iron, nickel, and chromium) in the foil alloy, various Curie point temperatures ranging from below 200 °C to over 1000 °C may be utilized by selection of the appropriate commercially-available foil. Figure 5 is a schematic of a commercial system in which the sample is on a ferromagnetic alloy filament which is centered in a stainless steel injector needle which pierces the GC septum. The photo, Figure 6, illustrates inserting the sample-containing ferromagnetic filament into the stainless steel injector needle. In order to be suitable for the sample type and analysis requirements, ferromagnetic filaments are available as wires, spirals, or tubes. The table in Figure 7 illustrates the reproducibility of three different peaks from five successive pyrograms of the same white automotive paint sample.

2.3 Microfurnace

In microfurnace pyrolysis systems the sample drops or is injected into the center of the reactor zone of a resistively heated, continuous mode microfurnace. Carrier gas sweeps the pyrolysis vapors into the column of the gas chromatograph. A diagram of the furnace assembly of a commercial system is illustrated in Figure 8. Injectors are available for both liquid and solid samples. The four pyrograms in Figure 9 illustrate how the pyrolysis temperature influences the distribution of pyrolysis products.

3 EXPERIMENTAL PARAMETERS

PY/GC must have run-to-run reproducibility to have any analytical value. Only those factors unique to pyrolysis will be considered here, but one should bear in mind that variations may also result from changes in the GC conditions (for example, injection port liner cleanliness and type, injector split/splitless conditions, transfer line and injection port temperatures, carrier gas (usually helium or nitrogen), carrier gas flow rate, column (type, length, diameter, cleanliness and bleed), temperature program, and the type of detector and the conditions for its operation). If a mass spectrometer is used as the detector for the gas chromatograph, it too may be a factor in a lack of

reproducibility and it is important that factors such as the tune program used, scan range and so on are the same. Various pyrolysis parameters have been studied by Ericsson$^{2}$ (sample type, temperature–time profile, temperature rise time, ambient temperature, carrier gas flow rate, and sample size). Tsuge et al.$^{3}$ considered transfer line and injection port heating effects, carrier gas effects (helium was better than nitrogen) and the effects of the inertness of capillary column materials and the buildup of tarry degradation products. Wampler and Levy$^{4,5}$ investigated the effects of various injection methods including cryogenic trapping.

4 QUALITY CONTROL

Wampler and Levy$^{4}$ have extensively investigated the problem of reproducibility in PY/GC. Just as it is routine practice in GC to inject a test mix of hydrocarbon standards daily, in a similar fashion, Wampler and Levy$^{6}$ recommend the use of a pyrolysis standard. They obtained

good results with Kraton® 1107, a styrene–isoprene copolymer.

5 FORENSIC SAMPLE TYPES

The application of PY/GC to forensic science samples has been reviewed by Wheals (1981), Challinor (1983), Saferstein (1985), Blackledge (1992), and Challinor in 1995.

5.1 Paint

Paint is by far the most common type of evidence sample compared by PY/GC. Paint traces may be exchanged in hit-and-run vehicle accidents and there is frequently an exchange of paint traces when tools such as screwdrivers, crowbars, and hammers are used in break-ins. If the paint traces have only a single layer, and assuming they match in terms of color, texture, and layer thickness, then the analyst need only make sure that the questioned and known samples for pyrolysis approximately match in terms of weight and dimensions (i.e. one sample should not be thin, long and narrow and the other thick and square). If the pyrolysis samples are placed in a quartz tube or boat which is then inserted into a coil of platinum wire, it is important that both questioned and known samples be placed in the center of the tube/boat, which is then placed into the coil so that the samples are at the midpoint of the coil’s length. The above admonitions are true for all solid samples. If the paint traces consist of two or more layers the analyst can either try to separate the individual layers and pyrolyze each separately, or they can pyrolyze the intact chips as long as questioned and known samples both have the same layers and roughly the same dimensions and layer thicknesses. This latter approach is frequently easier since it may be difficult to separate the layers without introducing contaminants.

5.2 Fibers

Although synthetic fibers may be identified/compared by methods such as polarized light microscopy and ultraviolet/visible/infrared microspectrophotometry, pyrolysis/capillary column GC in some cases may be able to show differences between different brands, especially if they are polymer blends.

For example, Almer (1988) used pyrolysis capillary GC to examine 63 acrylic and 22 modacrylic fibers from various manufacturers. Differences were seen because “acrylics can contain up to almost 15% of non-acrylonitrile copolymers, and modacrylics can have about 65% non-acrylonitrile copolymers.” On the basis of variations in peak proportions and extra peaks, she was able to subclassify the acrylics into nine groups (not shown) and the modacrylics into six groups (Figure 10).

5.3 Rubber and Plastic

Rubber and plastic bumper guard and trim material may be exchanged in vehicle accidents; acts such as kicking in a door may also leave traces of rubber/plastic from shoe soles and rubber traces may be left on knives used in tire slashings. Hu reported a two-stage method for compounded rubber products that first produces a chromatogram of any volatile materials (such as residual solvent traces from the compounding process) and then produces a pyrogram. Hu’s method has greater reproducibility and also produces more...
Analytical conditions

5.4 Photocopy Toners
Although different brands of toner on photocopy pages may be distinguished by Fourier transform infrared spectroscopy, excellent discrimination may also be achieved with pyrolysis capillary column GC.\textsuperscript{19,20}

5.5 Adhesives and Tapes with Adhesive Backings
Adhesive traces and tapes such as duct tape, electrical tape, and masking tape may be important evidence. Subsequent to nondestructive examination methods such as Fourier transform infrared microscopy, excellent reproducibility and discrimination may be provided by pyrolysis capillary column GC.\textsuperscript{19–24}

5.6 Other
Other less commonly encountered forensic sample types that have been examined by pyrolysis methods include different types of wood,\textsuperscript{25} chewing gum,\textsuperscript{26} natural gums, waxes, and resins,\textsuperscript{27} and adult and fetal bloodstains.\textsuperscript{28} Although hair,\textsuperscript{29,30} and different brands of smokeless powder\textsuperscript{31} have been examined, little discrimination was provided by PY/GC.

6 SIMULTANEOUS PYROLYSIS ALKYLLATION
Challinor\textsuperscript{32–34} has extensively studied a PY/GC technique where simultaneous with pyrolysis the pyrolysis products react with a derivatizing agent. In general the method is used with oxygen-containing macromolecular material which is susceptible to hydrolysis with subsequent alkylation. For suitable samples the method provides more structural information about polar components and greater sensitivity. Figure 12 illustrates the pyrogram of an epoxy resin by conventional pyrolysis (top), and then when the same material is subjected to simultaneous pyrolysis methylation using tetramethylammonium hydroxide (TMAH) as a derivatizing agent.

Challinor refers to this simultaneous pyrolysis derivatization reaction as “thermally assisted hydrolysis and methylation” (THM). Challinor\textsuperscript{35} described four criminal cases in which his THM procedure produced important findings:

- “The THM reaction is particularly suited to the identification of trace quantities of lipid-containing material such as cosmetic products. A multiple murder, where a fingerprint in a cosmetic body lotion was left by a suspect at the scene, was solved by using this application. The suspect was a known associate of the family victims and, therefore, [the print was] not of great significance. However, body swabs from the victims, who had been sexually assaulted, were examined and found to contain traces of the same body lotion as found in the fingerprint. The suspect confessed to the crime when confronted with this evidence”.

information for forensic comparisons. Figure 11 shows the results of this method used on questioned and known rubber bumper guard samples from a hit-and-run vehicle investigation.\textsuperscript{13}
Pyrolysis temperature 600 °C–700 °C, Column 25QC3/BP1/0.5, Length 25 m, Inside diameter 0.32 mm, Stationary phase cross-linked methyl silicone, BP1, Film thickness 0.5 µm.

Initial temperature 40 °C for 1 min

Program rate 10 °C min, Final temperature 130 °C for 1 min, Detector flame ionization, Carrier gas hydrogen, Linear carrier velocity 35 cm s⁻¹ at 40 °C, Split ratio 100:1, Injection mode pyrolysis split, Sensitivity 256 × 10⁻¹² AFS, Sample n-butylbenzene in pentane (2.5% v/v), Injection volume 0.4 µL, Pressure differential 2 psi.

Figure 9 Pyrolysis in a furnace-type pyrolyzer (PYROJECTOR®) of an n-butylbenzene sample in pentane (2.5% v/v) at four different pyrolysis temperatures, pyrogram (a) 600 °C, (b) 700 °C (c) 800 °C, (d) 900 °C. Components 1 pentane, 2 benzene, 3 toluene, 4 ethylbenzene, 5 styrene, 6 n-propylbenzene, 7 n-butylbenzene. (Reproduced by permission of Scientific Glass Engineering Incorporated, Austin, TX, USA.)

- “The female proprietor of a gift shop was brutally murdered with a blunt metal instrument. Minute traces of a blue paint were found in the head wounds of the victim. The paint binder was identified as an alkyd enamel by THM/GC/MS (mass spectrometry) using selected ion monitoring for dimethyl phthalate (m/z 163). Two peaks, corresponding to the ortho and iso-isomers were detected indicating that the alkyd enamel was a mixed polybasic acid type. This type of alkyd is often used in industrial coatings and could have been found on a tool. The alleged offender admitted that he had hit the victim with a blue painted adjustable spanner [crescent wrench]”.
- “Fragments of light brown vegetable matter were found in the head wounds of a young person attacked by youths with a cricket bat. The fragment of vegetable matter was identified by THM/GC/MS and pyrolysis of a 1% aqueous TMAH extract as wood belonging to the genus Salix (willow) and was consistent with originating from the cricket bat”.
- “The driver of a car, which had stopped due to mechanical failure, was badly injured by another vehicle while he was standing by his vehicle. The suspect drove away without stopping but was eventually apprehended. Black smears, identified by THM/GC/MS as polyethylene terephthalate and matching the victim’s polyester trousers, were found on the paintwork of the suspect vehicle. As a result, the suspect pleaded guilty in Court”.

7 MASS SPECTROMETRY DETECTION

Poor inter- and intralab reproducibility and an inability to create computer-searchable databases are deficiencies

frequently sited for PY/GC. Such deficiencies are hard to overcome when GC detectors such as flame ionization are used, and sample comparisons are largely based on pattern matching. However, a basis for a reliable computer-searchable database exists if good separation of the pyrolysis products is achieved by capillary column GC and then the essentially pure peaks are identified by their mass spectra.36 For example, Figure 13 shows the total ion chromatograms obtained from the pyrolysis of four 1995 black automotive paints.37 As shown in Table 1, most of the pyrogram peaks could be identified from their mass spectra. In some cases it is not necessary to pass the pyrolysis vapors through a gas chromatograph first. Direct pyrolysis/MS eliminates the variables introduced by the GC.

PY/GC/MS (pyrolysis gas chromatography/mass spectrometry) was one of several analytical techniques employed by Sandia National Laboratories (SNL) to
refute the Navy’s contention that the explosion in 1989 in a 16-inch gun turret of the battleship *U.S.S. Iowa*, which killed 47 crew members, was caused by a chemical ignition device that a suicidal guncrew member had placed between powder bags about to be rammed into the breech.\(^{38,39}\)

Along with other traces, the Navy had found glycols and a single fragment of polyethylene–polyethylene terephthalate (PE-PET). The Navy reasoned that the glycols came from brake fluid or a similar material and that the PE-PET fragment came from a plastic food bag. They postulated an ignition device containing calcium hypochlorite, brake fluid, and steel wool all contained in a plastic bag.

However, SNL pointed out that glycols are present in Break-Free CLP®, a liquid that was regularly used for maintenance of the 16-inch guns. SNL found that Dacron® fibers covered with Break-Free CLP® produced a PY/GC/MS spectrum indistinguishable from that of the PE-PET fragment, and that Dacron® fibers were in a brush used to clean the guns.

### 8 DATA INTERPRETATION

Although for complex pyrograms capillary column GC does a much better job of separating the individual pyrolysis products than packed columns, the length and

The complexity of the patterns can make difficult the visual comparison of questioned and known samples. The use of discriminant analysis methods such as principal component analysis and cluster analysis may aid in data analysis and the discrimination of samples by pyrolysis capillary column GC or PY/GC/MS.

9 ANALYSIS PLAN CONSIDERATIONS

Samples for forensic science analysis and comparison are frequently quite limited in amount and possibly contaminated by extraneous materials. These factors must be taken into consideration when developing an analysis plan. Pyrolysis methods will destroy that portion of the sample that was examined. The original sample must be photographed first. If the amount of sample is quite limited it is important to consider first analytical tests that are nondestructive. These could include examination with stereobinocular microscope, polarized light microscope, and tests for fluorescence when irradiated at various wavelengths. Sometimes a sample that was tested by other methods may be recovered and examined by pyrolysis methods just as long as the questioned and known samples were treated in the same way. For example, samples that were carbon- or gold-coated for examination by scanning electron microscopy/energy dispersive spectroscopy (elemental analysis), might still be recovered and examined by PY/GC. To obtain their infrared spectra, paint samples may be ground up with KBr and pressed into a pellet, but afterwards the intact pellets may be recovered and directly placed in quartz tubes for examination by PY/GC. To obtain their infrared spectra, paint samples may be ground up with KBr and pressed into a pellet, but afterwards the intact pellets may be recovered and directly placed in quartz tubes for examination by PY/GC. Scanning electron microscopy is providing increasingly definitive solutions to criminal problems since its commercial debut in 1965. This has been due to the ability of the scanning electron microscope (SEM) to simultaneously produce several electron probe-induced signals from the specimen, which generate readily interpretable images of surface topography and material composition. The successful applications of these signals are determined by sample preparation and instrumental parameters. No other microbeam technology combines high resolution (2–5 nm) of the topographic (secondary) electrons with large depth of field for three-dimensional viewing. The SEM is indeed ideal for stereomicroscopy. The versatility of the SEM stems from its additional capability to process each specimen signal by various contrast enhancement methods, such as line scanning, deflection modulation (DM), area mapping, etc. These methods allow an intuitive, stylistic, and synthetic analysis of the image and are ideal for quality control analysis. Digital SEMs have pioneered in automated image processing and unattended search and analysis of particulates. The combined SEM and energy-dispersive X-ray microanalysis (EDX) is the most definitive technique in testing for gunshot residue (GSR) particles, collected by the glue-lift technique. In the analyses of other trace evidence, such as hair and fibers, in physical matching, and in nondestructive elemental analysis of physical evidence, the SEM/EDX is the most efficient of...
all microbeam technologies. From firearms, bullet wounds and human bones, to plants, pollen and fungi, the list of criminal evidence examined by SEM/EDX is endless. However, the SEM/EDX is not ideal for quantitative analysis of elements present as traces (<1% w/w). The SEM lacks the three-dimensional sectioning abilities of scanning beam confocal microscopes. The imaging capabilities of the SEM surpass these limitations. The SEM is, therefore, a major tool in forensic research and investigation.

1 INTRODUCTION

SEMs use a finely focused primary beam of electrons (energy 5–30 kV) to make sweeps as a raster does across the specimen surface in synchronization with a cathode ray tube (CRT). As the primary electrons impinge on the specimen, a multitude of electron-beam-induced signals are generated within the specimen and from the specimen surfaces. Of these, the most important signals are secondary electrons (SEs), backscattered electrons (BSEs), characteristic X-ray photons (i.e. X-rays), and cathodoluminescence (CL). Each signal is detected and amplified to modulate the brightness of the CRT i.e. the SEM video monitor. The resultant information in each signal is obtained as an image of the specimen. Several of these signals may be recorded concurrently. These images can be obtained separately or in superimposition. The major advantage of the SEM is the high resolution obtainable with the SE, or topographic electrons. Another important advantage of the SEM is its large depth of field. The large depth of field and the shadow relief effect of the SE and BSE electron contrasts make the SEM images appear three-dimensional. Therefore, the SEM is also ideal for stereomicroscopy. The combined SEM/EDX technique is indispensable for fast, nondestructive, physicochemical analysis of trace evidence and solid objects of any size. Environmental SEMs are now able to study corrosion, catalysis and condensation problems at high (atmospheric) pressure. Digital SEMs allow automated image processing and unattended search and analysis of particulates. The intrinsic drawback of the SEM is that it lacks the three-dimensional sectioning abilities of scanning beam confocal microscopes. The SEM/EDX is not ideal for quantitative analysis of elements present as traces. Energy-dispersive X-rays are subject to the matrix effects of Z (the atomic number), absorption, and fluorescence, and a high Bremsstrahlung continuum for low-atomic-number elements. These effects reduce the ability of the SEM/EDX to detect an element below a minimum detection limit (MDL) (0.1–0.3% w/w).

2 HISTORY

The history of the SEM started long before Professor C.W. Oatley introduced the concept of an SEM in 1948 to the department of Electrical Engineering in the University of Cambridge in England. Three German physicists who laid down theories and designs of electron optics were H. Stintzing, M. Knoll, and M. Von Ardenne. Stintzing first applied for a patent on the designs of electron optics on May 13, 1927 and his application (German patent number 485,155) was granted in October of 1929. In 1935 Knoll first proposed the principle of the SEM. In 1938 Von Ardenne first built a scanning transmission electron microscope (STEM) by adding scan coils to a transmission electron microscope (TEM). The outpouring of interest in Germany in the development of the TEM and the outbreak of war put an end to the work of these physicists. The SEM had to be developed in the laboratory of Professor Oatley in the hands of his able doctoral students, D. McMullan, K.C.A. Smith, T.E. Everhart, O.C. Wells, R.F.W. Pease and others. Oatley and McMullan built their first SEM in 1952. This instrument was able to produce a resolution of 50 nm (50 Å). By 1963 R.F.W. Pease built a system (SEMV – the fifth SEM) which became the prototype of the Cambridge Scientific Instruments Mark I Stereoscan®. A.D.G. Stewart, chief engineer at Cambridge Instruments Ltd (England), who was once a student of Professor Oatley, commercialized this model of SEM in 1965. Since this commercial debut of the SEM, many technological advances have been made to improve the instrumentation and performance. Of these advances the notable ones are the developments of the lanthanum hexaboride (LaB₆) cathode, the field emission gun, and associated high-vacuum system (all in 1969) and the digital imaging, image processing, and automation of the SEM in 1976. The years 1965–1968 also marked the advents of wavelength-dispersive spectrometry (WDS) and energy-dispersive spectrometry (EDS) of characteristic X-rays, and their coupling to the SEM and the electron probe microanalyzer (EPMA), which is frequently referred to as the electron microprobe. Historically, the SEM and the EPMA evolved as separate instruments although these two instruments are similar. They differ mainly in the manners they are used, i.e. one for scanning and the other for fixed beam analysis.

3 SAMPLE PREPARATION AND INSTRUMENTAL PARAMETERS

Sample preparation for the SEM and instrumental parameters are keys to successful applications of the signals arising from SE, BSE, X-rays, and CL. Each
signal seems to have a preference for certain sample characteristics and substrate or mounting materials. With the SE electrons, the imaging of highly irregular and convoluted objects is as much of an art as a science. With characteristic X-rays in microanalysis, the sample surface must be flat so that matrix effects due to Z, absorption, and fluorescence are minimal.\(^5\) This is also true for the BSE signal, giving Z contrast with normal incidence and high take-off angles, because the BSE signals producing amplitude contrast (i.e. topography) are minimal with a flat surface. At oblique incidence and low take-off angles the Z contrast vanishes and the amplitude contrast remains.\(^8,9\) Most adhesive tapes and conducting paints used to mount SEM samples for SE and BSE imaging are cathodoluminescent. One must consider noncathodoluminescent substrate and mounting materials for CL imaging.\(^10\)

A variety of procedures are generally used to prepare inorganic materials for SEM.\(^5,11\) Metallic specimens are prepared according to the type of information to be obtained from the specimen. Biological, organic, polymeric, and hydrated materials must be preserved by fixation, dehydration, drying, and coating.\(^12\) Critical-point drying (CPD) is suitable for most biological objects\(^13,14\) except membranous organelles like mitochondria and specimens containing a polysaccharide surface coat (e.g. yeast and other fungi).\(^15\) Freeze drying is also suitable for all types of biological specimens.\(^12\) An authoritative article on general procedures for specimen mounting for the SEM is that by Murphy.\(^16\) The following section outlines only certain procedures used by this author to prepare forensic materials for SEM/EDX analysis. Details of these and specific procedures of several forensic, occupational, and environmental health practitioners have been compiled elsewhere.\(^17\)

### 3.1 Trace Evidence

Polished carbon planchets (diameter 13 mm or 0.5 in; thickness 3 mm or 0.125 in; Ernest F. Fullam, Inc.) are perhaps the most suitable substrates for the SEM/EDX analysis of trace evidence such as GSR particles.\(^18\) These polished carbon planchets are more expensive than their precursors – the highly coarse graphite planchets. The graphite planchets are smoothened by grinding with silicon carbide papers. These smooth planchets are further polished by using some polishing compounds. A typical grinding and polishing sequence might be 320, 400, 600 grit silicon carbide papers followed by 3 µm, 1 µm and 0.25 µm alumina or gold or diamond dusts.\(^5\) This standard metallographic work may be done manually or by using an automated rotating belt on a wheel. The planchets are cleaned with soap and water in an ultrasonic cleaner. A further sonication with petroleum ether or methanol removes the remaining carbon dusts from these polished carbon planchets.

### 3.2 Gunshot Residue

For GSR collection by the modified glue-lift technique,\(^19–23\) these polished carbon planchets are mounted with adhesive tapes on the 13-mm diameter sanded top of hat-like plastic thimbles (Caplug\(^8\)). These plastic thimbles are inexpensive. They also allow ease of operation because the collector can be lifted by inserting a finger into the thimble. A dilute (1 : 3 v/v) solution of Rubber Cement\(^8\) (Stafford-Reeves, Inc.; Carter’s Ink Co.) in toluene is applied as one or two droplets to the polished surface of the planchet and the glue solution is allowed to spread uniformly. The excess liquid is soaked off the edges of the planchet with a torn filter paper. The thimble supporting this glue-lift disk is then covered from the top with an unsanded thimble. This collector set is allowed to stand inside a transparent cylindrical plastic box and is held in place by the snap-in (tight-fitting) cover of the box (height 2.54 cm). Four such boxes are stored in a square plastic box (height 3.2 cm). The GSR kit consists of this box, the collection procedure, and a pair of polyethylene gloves, all packaged into a rectangular paper box as shown in Figure 1. The New York State Police have used these kits in the field during the period 1980–1989.\(^20,21,23\) With a finger inserted into a collector thimble, the attached planchet was gently touched five times to a specific area: either the palm or the back of a particular hand, as marked on the side of each thimble. Thus, two collections were
made from each hand, with the total collections being four per subject or per test firing. Optimal tackiness, thickness, and smoothness of the glue layer results in selective rejection of interfering skin cells and sufficient collection of GSR spheroids having condensate or molten morphologies.\textsuperscript{(18,19)} Figure 2 shows GSR distribution and Figures 3–6 the morphology and elemental make-up of GSR.

The shelf-life (14 months or more) of glue-lift disks (GSR kits) improves remarkably when toluene is used instead of 1,1,1-trichloroethane as the solvent to dilute the stock glue. This particular glue contains traces of silicon.\textsuperscript{(18)} Scotch\textsuperscript{®} brand 465 transfer tape also

\textbf{Figure 2} SE image of GSR distribution by glue-lift. Collection by only three touches from the web area (between thumb and forefinger) of the test shooter's hand after one firing. The shooter's hands and the gun were both precleaned prior to firing.\textsuperscript{(18–20)} The field contains two GSR spheroids (PbSbBa), three binary spheroids (2BaSb + 1PbSb) and six monomers (Pb). The field represents only 6% of a 1.5-mm diameter marked circle (search area). In the glue-lift technique four such circles are usually examined per collector disk to render an opinion. Gun, 0.38 caliber revolver; ammunition, Remington 38 spl 200 grain lead bullet; magnification, 550×; bar = 20µm; 20 kV.

\textbf{Figure 3} BSE image (Z contrast) of GSR distribution by glue-lift. Collection by five touches from the back of a subject's (victim) right hand. The field shows one GSR and 13 monomers (Pb) of diameters in the range 0.1–0.8µm. The back of the hand had more than 125 particles (i.e. >8 PbSbBa + 27 PbSb + 89 Pb/Ba in four circles; diameters were 0.1–4.0µm). These were mainly smooth regular spheroids – a sign of breech GSR! See the examples in Figure 4 and elsewhere.\textsuperscript{(23)} Case, a homicide; gun, 0.32 caliber 5 shot Harrington and Richardson revolver; ammunition, 0.32 caliber lead bullet; magnification, 7930×; bar, 1 µm; 20 kV.

\textbf{Figure 4} (a) SE image of a regular GSR spheroid of smooth surface topography with two nodules on its head and (b) its EDX spectrum. GSR diameter, 1.9µm; composition, PbBaSb < CaSiFe. This and other smooth GSRS were detected on the right hand back of the subject in Figure 3. These fluid GSR droplets were forced to escape through the breeches by the backward thrust of the propellant gas mixture. Case, gun and ammunition as for Figure 3; magnification, 24 000×; bar, 1 µm; 20 kV.
Figure 5 (a) SE image of a Peeled-orange GSR of irregular surface topography and (b) its EDX spectrum. GSR diameter 15.5 µm. Peeled-orange GSR has a Ba–Sb core and an outer layer of Pb (see Basu and Ferriss\textsuperscript{18} and Basu\textsuperscript{19}). This and other GSRs of irregular surface topography were detected along with bullet fragments and Pb residues on both hands (back of each hand) of the subject (victim). These are the characteristics of rebound muzzle-blast residues. The semisolid muzzle-blast GSR captures idle residues and contaminants of the barrel on their surfaces. Case, a homicide; gun, 12 gauge American Eagle model 60 G shotgun; ammunition, 12 gauge Remington rifled slug (Pb); magnification, 4500×; bar, 2 µm; 20 kV.

contains a negligible amount of barium and silicon. This tape is used to mount specimens greater than 1 mm in width. Large objects such as bullets and cartridge cases are mounted on special types of specimen holders.\textsuperscript{16}

3.3 Paint Chips, Glass, and Metallic Fragments

Paint chips as small as 1 × 1 mm are held in droplets of glue solution (dilution 1/5, solvent 1,1,1-trichloroethane) until the solvent evaporates and the glue holds the paint chips on edge, i.e. perpendicular to the surface of the polished carbon planchet. This method has been particularly suitable for X-ray dot mapping of elements in the successive layers of paint chips.\textsuperscript{24} Comparative elemental and topographic analyses of trace evidence, such as fragments of glass, are performed by mounting the evidence and the control substance on two halves of the same glue-lift disk separated by a diameter. This diameter and the item numbers of the evidence and the control are scribed on the glue layer with the sharp end of a tweezer (Figure 7). The glue-lift disks are also used to lift a monolayer of particulates, granules, metallic dusts and/or scrapings.

Figure 6 (a) SE image of a regular GSR spheroid of smooth surface topography and (b) its EDX spectrum. GSR diameter 4.5 µm. A total of 21 such smooth GSRs were detected on the right hand back and four on the left back of the subject (suspect). Case, a homicide; gun, 0.38 caliber Rossi revolver; ammunition, Winchester 0.38 caliber centerfire cartridge; magnification, 10 000×; bar, 1 µm; 20 kV.
3.4 Explosive and Arson Residues

The interelement effect\(^{4–7,25,26}\) of X-ray absorption is minimized when the specimen is well-spread as a thin layer on a smooth, spectroscopically pure substrate, the element of which (e.g. carbon) cannot be detected. Therefore, if the sample is in a suspension, a small volume of it is withdrawn with a Pasteur pipet and settled as a droplet on a polished carbon planchet. The planchet is air-dried (Figure 8). This method is used to detect lead and bromine containing gasoline, arson residues, black powders, pyrotechnique residues, and inorganic explosive residues.

3.5 Hairs and Fibers

Cut segments of hairs and fibers are arranged in an array on a smooth glassine paper. These are lifted by one touch of the glue-lift disk (Figure 9). Carbon rods or cylinders are also used to wrap hairs around them. When the glue layer is not desirable (as in CL studies) the cut segments of hair are attached to a polished carbon planchet with a clipper.\(^{10}\) The specimen planchet are usually affixed to an aluminum pin (13 mm or 0.5 in diameter) for carbon coating and further examination in the SEM. When necessary, the disk is separated from the aluminum pin with a scalpel. A convenient alternative to this is the use of pin-type polished carbon mounts.

3.6 Mounting, Embedding and Sectioning of Gunshot Residue Particulates

The distribution of elements within the interiors of particulates is directly related to their origin and/or the process of their formation and growth by the condensation of vapors. These problems can be solved by sectioning particulates and performing X-ray dot mappings of the elements on the cross-sections of the particulates. The following method of mounting, embedding and sectioning was used to examine the formation of GSR particles\(^{19}\) and can be used for other particulates or residues. The embedding compounds are Epoxy-812, two hardeners, namely nadic methyl anhydride and dodecenyl succinic anhydride, and DMP-30, the accelerating compound (Ernest F. Fullam\(^{8}\)). The first three compounds are mixed and applied on several 13 × 102-mm cut pieces
of aluminum foil (Reynolds Wrap), or 8 × 100-mm pieces of Scotch® copper tape. These are fixed in arrays on two cardboards. One is held in close proximity (5 mm) to the breech of a firearm, while the other one is held horizontally about 100 mm below the muzzle as the gun is discharged three to five times. The emanated GSR is captured by the target aluminum foils or copper tapes. Large quantities of primer GSR are obtained by shaking primer cups of expended bullet casings. These are sieved through a 300-µm aperture sieve and spread as a monolayer on the adhesive layer of Scotch® copper tape. The accelerating compound (DMP-30) is added to the epoxy mixture and this embedding medium is applied on the particles of the foils and tapes. Each foil or tape is tightly rolled over a piece of plastic tubing, cut on both sides to make spools. The aluminum or copper spool is inserted into a beam capsule filled with the embedding mixture. The capsule is covered and epoxy is allowed to harden at 65 °C for 6 h and then for another 5 days at room temperature. The capsules are sectioned in a microtome (Will Corp.®) with a steel blade at an angle of 75° (Figure 10a). Figure 10(b) shows a sectioned GSR particle.

3.7 Specimen Coating, Energy-dispersive X-ray Microanalysis and Scanning Electron Microscope Parameters

Whether the mounted specimen should be vacuum coated with carbon (thickness 20 nm) or with a heavy metal (Au, Pt–C, etc.; thickness 1–3 nm), or whether the coating should be avoided, all depends on the purpose of the experiment, the conductivity of the specimen, and on the charging effects. The specimen must always remain grounded. The sample disk must be turned towards the X-ray detector (tilt 30–45°) and be in line with it to produce optimal X-ray counts (about 500–1500 counts per second). The maximal integral (pile-up) count, for example, with the EDAX® (Model 707A) memory is 263,744 (i.e. 219). This number should not be exceeded. The conditions (SEM/EDX) required for X-ray dot mapping of the elements are described elsewhere. These SEM/EDX studies must be preceded by a thorough search for the sources of spurious metallic emissions in the SEM chamber. The brass surfaces of solid-state (“quad”) backscatter detectors around the aperture of the final lens are the main sources of X-rays due to copper and zinc. The major source of aluminum X-rays is the collimator window of the X-ray detector. These spurious X-ray emissions are caused by high-energy (>10 kV) BSEs reaching those surfaces from the specimen mount. Therefore these surfaces must be heavily coated with evaporated carbon (thickness > 10 µm). This precaution allows the specimens to be examined in close proximity (3 cm) of the collimator window of the X-ray detector. These increases the take-off angles and collection of X-rays. All specimens are examined with 20-kV electrons at an emission current of 75–90 nA. The corresponding beam currents are 0.1–10 nA for a 100–200 µm objective aperture. Accurate measures of the electron beam current are obtained at the specimen level by using a Faraday cup. The magnification standards used to calibrate the SEM are 1 µm diameter latex spheres (Figure 11) and a waffle grating. Evaporated gold particles on a carbon film and evaporated gold film on a magnetic recording tape are used to obtain the SE images for any given conditions of the SEM. These images are examined to obtain the resolution of the SEM. This resolution test is crucial during installation of an SEM, and afterwards as the observed resolution may change due to stray electric and magnetic fields and vibrations.
4 SCANNING ELECTRON MICROSCOPE SIGNALS AND THEIR FORENSIC APPLICATIONS

An authoritative review of SEM in forensic science, though dated, is that by Taylor,(28) Taylor and Noguchi,(29) and Pfister(30) have published comprehensive bibliographic updates of forensic applications of SEM up to 1979 and 1982, respectively. Forensic science has advanced since then hand in hand with the technology and understanding of the SEM. Forensic applications of the signals arising from SE, BSE, characteristic X-rays, and CL are identified.

4.1 Secondary Electrons and Surface Topography

As their energies are low (0–50 eV), SEs escape from only a very thin layer of the specimen surface. Because many of them are reabsorbed by the specimen itself, the effective area of SE emission is close to the diameter of the incident electron probe.(31,32) No matter how irregular the specimen is these electrons are collected from every detail of the specimen surfaces within the scanned width of the image.

4.1.1 Detection Limits and Ranges

The result of this superior collection of SEs is the combination of superb depth of field (300–500 times that of a light microscope) and high resolution (7 nm or better) at wide ranges of continuously variable magnifications (20–500,000×).(31–34) Resolutions of the order of 2–5 nm are now usually quoted for commercial instruments.

4.1.2 Applications

This SE imaging mode has been used for the examination of toolmarks, such as firing pin impressions on cartridge cases,(35–39) bullet markings,(35,40,41) inscriptions on coins,(42) staple impressions,(43) toolmarks on cut ends of wires,(39) and other surface marks.(44) The physical matching of two broken surfaces (e.g. glass, ceramics, and vehicle filaments),(45–51) comparison between chemically modified hairs(52) and fibers,(40) and characterization of hairs(53–55) based upon surface texture, dimensional width and mass distribution in cross-sections have been possible. Pelton(56) has used this imaging mode to determine the cause of fiber damage using models based on single fiber fracture, such as lateral compression, clean-cut and cap, etc. Microfibers can also be identified using SEs.(57) Surface analysis using the SE mode has identified a musket shot dated between 1645 and 1655, found in historic St Mary’s City in Maryland.(58) Morgan(59) has used SEs to visualize the restored serial number of a firearm. Using the SE micrographs of magnetically separated particles formed by abrasive cutting versus oxygen cutting of the same safe, Zeichner(60) has shown that debris of the two cutting processes have distinguishable characteristics. In a recent study by McDermott(61) topographic analysis of metal particles generated by a grinder fitted with an abrasive disk has linked some suspects with three criminal cases as per Locard’s(62) exchange principle. Discrimination of ceramics based on microstructures is now possible using SEs with computerized image analysis to determine grain size distribution, and X-ray diffraction patterns.(63) Topographic analysis in the SEM shows that suspected marijuana leaves, hashish, heroin crystals and mixtures of narcotics and sands, all recovered from crime scenes, have identifiable surface textures and/or characteristics.(41,64,65) It should be noted that surface textures and characteristics are enhanced by a heavy metal (e.g. gold) coating because the coefficient of SE emission for a heavy metal is greater than that of carbon, the heavy metal being a higher-atomic-number element.(66) Unless specified otherwise, these organic and bioorganic physical evidence specimens are usually examined in the SEM after gold or palladium coating with a sputter coater. Quantitative support to these dimensional studies can be given by obtaining stereopairs of the specimen image.(67) In fact, this technique has been successfully applied to the examination of line crossings.(68)

Recent years have observed breakthrough applications of SEM imaging to visible(24) and latent(69–71) fingerprints. The development of latent fingerprints requires the use of magnetic fluxes on paper(69) and the deposition of palladium or gold on cartridges.(70,71) The SE imaging has found numerous applications in various branches of forensic medicine. Bohm(72) first utilized the SEM to examine skin injuries and bullet wounds. These studies
were extended to routine autopsy examinations by his group. The SE imaging has solved many problems associated with thermal denaturation of bone collagens and changes of color, morphology, crystal structure, and shrinkage of burnt bones and teeth. Experimentally-controlled heat-treated human bones have shown that ultrastructural features are quite specific to the associated temperature transitions within 200° C and the age of the deceased. The SEM image patterns of burned or carbonized human remains also correlate with the furnace temperatures between 150 and 1150° C. The SEM images have been used for estimating age of nonburned archaeological samples from vertebrae and normal ribs and other skeletal remains.

Botany had been an underutilized resource in forensic investigation. The SE imaging has made new advances in this area. Plants, pollen, fungi, strawberry, and olive seeds are now being used as both weapons against, and evidence of, criminal acts. The trichomes owe their presence to postcrash, not precrash, events. The SEM has contributed to the development of a simple and rapid method for processing organ and water samples for identification of diatoms and for diagnosis of drowning. Recent applications of the SEM in forensic entomology include the detection of chironomid larvae in a homicide victim submersed in water. Other entomological evidence has also been identified using the SE imaging mode. The SEM is now being used in forensic forestry to determine the origin and cause of fire by an examination of urban airborne particulate matter.

The SEM has made an unusual contribution to DNA identification by the polymerase chain reaction (PCR). The adhesive tape-lift stubs are normally used for collection and detection of GSR with SEM/EDX to solve shooting crimes. Because the adhesive tape lifts profuse amounts of skin cells, which bury the GSR particles, the attribution to a specific suspect becomes uncertain, the epidermal cells on the stubs may be used to extract the DNA, which is then amplified by PCR and typed. The Drugfire Program of the Federal Bureau of Investigation (FBI) can strongly benefit from innovative applications of the SEM potential in computerized imaging. Commercial SEMs (e.g. CamScan) with a large specimen chamber allow comparative studies of bullets and cartridge cases. These systems can surpass the light microscopic limitations of the Integrated Ballistic Identification System (IBIS) which are currently in use by the Bureau of Alcohol, Tobacco and Firearms and many state crime laboratories and their networks in the United States. David has applied the SEM to bite-mark analysis. He has shown that the SEM can readily demonstrate individual characteristics in carbon-coated bite marks. The high topographic contrast achievable with a heavy metal (e.g. chromium) coating and the high resolution and superb depth of field obtainable in the SEM, make possible the effective use of stereo techniques in these diverse forensic studies.

4.2 Backscattered Electrons and Atomic Number Contrast

BSEs are high-energy (≥50 eV) elastically scattered electrons which emerge from a larger volume (greater depth) of a specimen. The images from these electrons are inferior in resolution to SE images. However, BSEs provide additional information because of their greater sensitivity to atomic number variations with the specimen. Currently this is referred to as compositional contrast.

4.2.1 Detection Limits and Ranges

The threshold equation based on the Rose criterion and the brightness of the electron gun forms the basis for estimating the detection limits and ranges of resolution in SEM images. One must first consider the type of contrast mechanism and the numerical value of contrast to be expected for a specimen. For a flat, polished sample consisting of alternating layers of aluminum and iron of various thickness viewed edge-on with BSE, we can calculate the Al–Fe contrast as C = 0.45 (45%). Assuming an average detection efficiency of 0.20, the threshold beam current needed to image this contrast in a 100-s frame is 1 x 10^-12 A, or 1 pA. The corresponding probe size can be calculated from the brightness equation. The brightness of a tungsten filament is 5 x 10^4 A cm^-2 sr^-1 at 20 keV and its divergence for a 200-μm aperture and 10-mm working distance is 10^-2 radians. The corresponding probe size is 2.8 nm. The actual probe size will enlarge to about 5–10 nm due to aberrations. The directionality of BSE causes penetration into the specimen and they undergo plural scattering before they are emitted from a larger volume. Therefore the limiting resolution with BSE is 20 nm or more under the conditions specified. For another specimen containing layers of platinum and gold, the atomic number contrast is only 0.0041 (0.41%). The threshold beam current for this contrast is 9.5 x 10^-9 A (9.5 nA). The probe diameter required to contain this current increases to 280 nm (0.28 μm). The corresponding resolution with BSE would be a few micrometers. The chemical compositional, mass thickness variation and the presence of edges thinner than the sampling depth of BSE and/or the range of incident beam electrons, are all taken into account to develop strategies for obtaining optimal BSE images.
4.2.2 Applications

Matricardi\textsuperscript{96} has used BSE imaging to examine glass fractures. Both SE and BSE imaging have been used to determine the sequence of intersecting lines.\textsuperscript{24,97,98} A cross-over of pencil lines is shown in Figures 12(a) and (b). The BSE image in Figure 12(a) was recorded first. The image in Figure 12(b) was recorded after the cross-over was rotated through 180°. Both these images show that line 2 has cut through line 1, which was drawn first.\textsuperscript{24}

4.3 Characteristic X-rays and Elemental Analysis

Chemical elements present in a specimen are characterized by their X-ray emissions. Nondestructive analysis of inorganic elements with $Z > 11$ (sodium) is performed either by EDS or by WDS. The chemical information can be obtained as a spectral read-out of the X-ray peaks of the detected elements. EDS is much faster than WDS and, therefore, EDS is mainly used by crime laboratories. However, the EDX spectra generated by EDS are less suitable for quantitative analysis than the wavelength-dispersive X-ray (WDX) spectra produced by WDS. WDS offers 10 times more resolution than does EDS and, therefore, WDS is mainly used with EPMA for research purposes.

4.3.1 Detection Limits and Ranges

The elements detected by SEM/EDX may occupy only a few cubic micrometers of sample volume.\textsuperscript{99} However, this capability should not be confused with the analytical ability of this technique. The MDL of an element in a matrix by SEM/EDX is about 0.1–0.3%. The corresponding values at the two-sigma confidence level (twice the background) is 0.2–0.6%. Flat-polished (not etched) elemental standards of the National Institute of Standards and Technology (NIST) are usually preferred for determination of MDLs.\textsuperscript{11} In the absence of these standards, seven to eight dissolved oxides of the Spectra-Tech\textsuperscript{8} elements are spread as a monolayer on precleaned polished carbon planchets (Figure 8). The selected elements are those that frequently occur in forensic or physical evidence, such as GSR (PbBaSb), bullets (PbCu) and paints (AlScCa, PbCr), etc. Four of these elements are studied at one time using a multiple pin holder. This allows the operating conditions of the SEM/EDX to remain the same for each element. The electron beam energy (voltage) is chosen to obtain an overvoltage (beam energy/critical ionization energy of the shell) of 2.0. A decrease in overvoltage below 2.0 reduces the amount of the incident electron beam energy made available for the production of characteristic X-rays and the energy range of the emitted X-rays. A beam energy of 20 keV is used for all pure elements and specimens as this beam energy is a good compromise between the need for adequate overvoltage and the need to minimize X-ray absorption in the specimen. The measured peak intensities are adjusted for background radiation by linear interpolation of the lower and higher energy ends of each Gaussian elemental peak, and by background extrapolation of the linear interpolations (i.e. within peaks) for a mixture of elements. The plots of background-corrected intensities ($\log_{10}$ of total counts per second) versus concentrations ($\log_{10}$ of w/w(%) ) of the element are fitted to straight lines by the least-squares approach. These plots show intercepts on the axis of concentration when the concentration is below 1% (w/w). These intercepts are the MDLs of the element at the X-ray lines being studied. These intercepts are smaller for K\textalpha lines but larger for K\textbeta lines. For example, the
MDLs of the Ga Kα and Kβ lines are about 0.012% and 0.04%, respectively. The existence of these MDLs (zero X-ray counts) is clear evidence that SEM/EDX or EDS must be avoided for trace (i.e. less than 1%) elemental analysis when the elements are in a matrix. The described method offers only crude estimates of MDLs and should not substitute the practice of using polished elemental standards. Unfortunately the lithium-drifted silicon EDS with a beryllium window cannot be applied to low-atomic-number elements (Ne, F, O, N, C, B, and Be). Windowless or thin-window EDS detectors allow access to X-ray lines below 1 keV and these systems are necessary for the analysis of these light elements.

The accuracy with which the X-ray peak intensities are converted to elemental concentrations depends on the chemical make-up and configuration (e.g. topography) of the sample, and on the access to a computer program that corrects for the interelement effects due to atomic number, absorption, and fluorescence (ZAF).\(^4\)\(^-\)\(^7\)\(^11\)\(^23\)\(^25\)\(^26\) Furthermore, the ZAF method is suitable only for homogeneous samples and when the specimen surfaces are polished enough (not etched) to minimize the erroneous X-ray absorption (e.g. topography or take-off angle effect). Also, application of the ZAF method requires that a value for the pure element intensity is obtained for every element in the sample. The ZAF method and other empirical approaches are more suitable for thin films and thin sections than for bulk samples. The SEM/EDX technique is limited to surface analysis, due to the lack of penetration of low-energy electrons (5–30 keV) into the specimen. Therefore, because the homogeneity aspect of physical evidence is often unknown, this analysis is only qualitative. With irregular and inhomogeneous specimens, several examinations are made and the X-ray intensities are corrected for the background X-ray radiation. Such examinations reveal basically the major (>10%) and the minor (>1%) elements detected in the sample, and whether or not two or more submitted samples (evidence and control) have the same general composition. Specific guidelines for automatic EDS analysis and WDS qualitative analysis are given elsewhere.\(^5\)\(^11\)

### 4.3.2 Applications of Simultaneous Secondary Electrons, Backscattered Electrons, and Energy-dispersive X-rays or Wavelength-dispersive X-rays

An important application of the signals described up to this point (i.e. BSEs, X-rays, and SEs) is the search and identification of GSR particles, as these particles are characterized by their constituent primer elements (lead, antimony, and barium),\(^18\)\(^-\)\(^23\)\(^100\)\(^-\)\(^114\) their specific spherical shape and condensed (molten) morphologies, both on the surfaces\(^18\)\(^,\)\(^19\)\(^101\)\(^-\)\(^105\)\(^,\)\(^107\) and in the interiors,\(^19\) and by their wide range of diameters – from submicrometer to 55 μm or more.\(^18\)\(^,\)\(^19\) These GSR particles are distinct from many environmental and occupational particles.\(^104\)\(^,\)\(^108\) The physical processes involved in GSR formation,\(^19\) in the transfer of elements from bullet to GSR,\(^111\) in the escape of GSR from the breeches and the muzzle of a gun, and their forced deposition on the firing hand(s) or any hand in close proximity,\(^21\)\(^,\)\(^22\) make GSR infallible physical evidence. Consequently, the density distribution\(^20\)\(^-\)\(^22\) of all deposited particles, including GSR (PbSbBa), and perhaps also their spatial distribution\(^113\) on the back of the shooting hand(s) have been an aid to reconstructing shooting crimes.\(^20\)\(^,\)\(^21\)\(^,\)\(^24\) The success rate of the SEM/EDX detection of GSR is incredibly high when precautions are taken against losses and transfers of GSR from the shooting hand(s).\(^23\) The yield of observable GSR on a specimen disk depends on the efficiency of the collection technique, such as glue-lift\(^18\)\(^-\)\(^23\) or tape-lift.\(^101\)\(^-\)\(^104\)\(^,\)\(^107\)\(^,\)\(^115\) Two methods of concentrating GSR from tape-lift disks are now available.\(^106\)\(^114\)\(^,\)\(^116\)

The tape-lift technique is essentially a skin (i.e. DNA) collection technique.\(^88\) The adhesive used in this technique is Scotch\(^\text{®}\) transfer tape (3M brand 465). This tape is 40–60 μm thick and very sticky.\(^18\) The aluminum stub containing this tape is usually dabbed on the shooter’s hand many times (>50), or until the stickiness of the adhesive is over. As a result the GSR particles collected in earlier touches are buried under epidermal cells and extraneous materials that pile up in subsequent touches. Very few of these GSR are made available for topographic identification using SE imaging.\(^18\)\(^,\)\(^103\) Only the high-energy BSEs and characteristic X-rays which escape the thin regions of these epidermal cells may register some of the particles, but not their real morphologies. This is being practised in automated GSR research and analysis.\(^112\)\(^-\)\(^116\)\(^-\)\(^122\) By applying plasma-ashing to tape-lifts of GSR, Sild and Pausak\(^47\) have shown that, as these epidermal cells are removed by ashing or burning, the GSR appear on the sample disks. This suggests that the GSR found on the tape-lift disks are mostly those particles lifted in the last few dabblings. The moist endodermal sides of the accumulated epidermal cells may have this lifting ability. However, the retention of these particles requires double carbon coating because the adhesive tape also cracks, makes blisters and pockets, and melts under the electron beam in the SEM.\(^18\)\(^,\)\(^47\)\(^,\)\(^103\)\(^,\)\(^115\)

As a result of these drawbacks tape-lift has the potential to generate many false positive, false negative, and inconclusive results. Obviously these cases require further DNA analysis using the collected epidermis.\(^88\) A recent report on GSR cases using the tape-lift technique shows that GSR positive samples containing one GSR, from two to five GSRs, and more than five GSRs were, respectively, 3.9%, 4.4%, and 1.7% of all submitted samples, with an
overall success rate of 10%. Of the GSR-positive suspects, 31% had only one GSR on their hands. In this and other casework assessments of automated GSR analysis using the tape-lift technique, the threshold level of GSR-positive cases happens to be one GSR. This threshold, consisting of either one “Unique” GSR or one “Consistent” GSR, originated from the research of the Aerospace Corporation. Stronger evidence is forthcoming to suggest that this threshold is highly ambiguous. The potential of secondary GSR transfer from police officers on to subjects has been tested. Forty-three officers were sampled with tape-lifts which were subsequently concentrated and analyzed by SEM/EDX. Three of these 43 officers had on their hands “Unique” GSR, each containing lead, barium and antimony. “Unique” GSR are spheroids of four different compositions (see Wolten et al.). These are (a) Pb, Sb and Ba; (b) Ba, Ca, Si with a trace of S; (c) Ba, Ca, Si with a trace of Pb if Cu and Zn are absent; (d) Sb and Ba. “Consistent” GSR, also caused “characteristic GSR”, especially if spheroidal but are not “unique” to it, are of the following five different compositions (see Wolten et al.): (a) Pb, Sb; (b) Pb, Ba; (c) Pb; (d) Ba, only if S is absent or only a trace; (e) Sb (rare). “Full” GSR (see Basu and Ferriss) are full complements of GSR spheroids each containing Sb, Ba and Pb. Fifteen other officers had particles containing at least one (Pb/Ba/Sb) or two (PbSb/SbBa/PbBa) of the three elements. Twenty-five officers had no GSR on their hands. This statistic suggests that one-GSR cases must be discarded. Alternatively, the hands of the arresting officers must be sampled. The current users of the tape-lift technique ignore the spherical shape, the condensation (e.g. homogeneity) characteristics and the molten features of GSR in their automated GSR analysis. The irony is that these GSR characteristics were introduced by the developers of the tape-lift technique. Furthermore, the discharge residues from cartridge-operated industrial tools (e.g. studguns), cap guns, and residues of some paints and fireworks may also contain one or more of the GSR elements.

The yield of GSR by only five touches of the glue-lift disk is usually sufficient for GSR detection and analysis by SEM/EDX. Figure 2 is an example of such collections from a test shooter’s hand at a low magnification. The field of view shown contains two GSR spheroids each containing PbSbBa, three binary spheroids containing BaSb (two) and PbSb (one), and six monomer spheroids containing only Pb. Figure 3 represents the collection from a subject’s (victim) right hand (back) at 7930× in a case submitted as a homicide. This glue-lift collector had hundreds of GSR in only one 1.5-mm diameter area of the disk. This case turned out to be a suicide based only on the GSR analysis. The glue-lift technique has been tested by officers and investigators of the New York State Police in several such cases. This technique has provided them with a wealth of information about their cases. Figure 3 also highlights that it is only the glue-lift that is able to collect the smallest of the smaller GSR particles as well as larger particles in a wide range of diameters (namely 0.1 – 55 µm). The tape-lift technique has never been able to produce such data of both quantity and quality.

The glue-lift technique has been applied to 298 cases (total number of kits 380) of the New York State Police with an overall success rate of 70.4%. This success rate does not include an additional 6.4% of the cases where in each case more than 25 binaries (PbSb/SbBa/BaPb) were detected along with bullet fragments and bullet residues on hands. None of these residues were “Full” or “Unique” GSR (PbSbBa) spheroids. They had the characteristics of muzzle-blast residues which usually contaminate a hand touching a discharged firearm at the muzzle. Similarly the additional 20.8% of the cases had in each case less than 25 binaries (PbSb/SbBa/BaPb) plus monomers (Pb/Sb/Ba). No opinion has been given in these cases because the detected particles were all contaminants. The success rates with suicides, suspected suicides, and joint homicides and suicides were 81%, 86%, and 90%, respectively. With homicides, assault, reckless endangerment, and prohibited use of firearms, the success rates were 54%, 57%, and 50% respectively. Definitive opinions, including specific hand positions in self-inflicted deaths, were given in many of the successful cases (66.4%). None of these opinions has been challenged or disproved. Figures 4 – 6 represent typical GSR detected in three submitted cases of homicides. Two of these cases turned out to be suicides based on the analysis of GSR morphologies and their distribution on the back of hands (Figures 4 and 5). These and other cases were guided by the established finding that regular GSR spheroids of smooth surface topography are infallible evidence of fresh breech GSR, namely the hand being on the trigger or in its close proximity at the instant of firing. These fresh GSR (PbSbBa) spheroids bounce and roll off the surfaces of the gun due to the pressure of the trigger blast. Conversely, these semisolid regular GSR become flatter and irregular as they strike the exposed surfaces of the gun. Only irregular GSR occur on the surfaces of the fired gun and these could be transferred to a nonshooter’s hand due to physical contact with the most contaminated areas of the fired weapon. The glue-lift threshold used (N) in these successful cases was 10, where N = 2 GSR + 8 binaries plus monomers (GSR = PbSbBa; binaries = PbSb/SbBa/BaPb; monomers = Pb/Sb/Ba). This threshold is much higher than the threshold used by the
users of tape-lift (i.e. one “Unique” or “Consistent” GSR).\(^{(109,117–123)}\) If one applies this threshold of tape-lift to casework using glue-lift, then the success rate would be 97.6%. The objective of the glue-lift development in SEM/EDX was to turn this cutting-edge technology into an investigative tool. The users of tape-lift cannot even imagine this fundamental potential of glue-lift even though they are searching for GSR in every case.

The threshold question avoids the ambiguity raised earlier with the tape-lift collection technique. This threshold is also consistent with the physical process of GSR condensation from its three major elemental vapors at a dynamic equilibrium\(^{(19)}\) and it is usually representative of the deposits found in test firings where no loss of these deposits is allowed (Figure 2). It is senseless to imagine that physical activity of the suspect shooter selectively removes the binaries (PbSb/SbBa/BaPb) and monomers (Pb/Sb/Ba) but retains only the “Full”\(^{(18)}\) or “Unique”\(^{(104)}\) GSR (PbSbBa) on hands, and vice versa. A further distinction between glue-lift and tape-lift is that glue-lift is able to show consistency in deposition per firing with precleaned guns, also known as the density distribution criterion and is, therefore, able to reconstruct shootings.\(^{(20–23)}\) This is beyond the reach of tape-lift because the collection efficiency of tape-lift is only 33%, whereas the collection efficiency of glue-lift is at least 84%. DeGaetano et al.\(^{(126)}\) used the glue-lift technique inappropriately by substituting the needed polished carbon planchets with the coarser smooth planchets because the polished carbon planchets cost four times more than the smooth planchets. They failed in their effort to make a good comparison between the two GSR collection techniques. If tape-lift is better than glue-lift, then the users of tape-lift should document thousands of GSRs per sample disk, not one or two.\(^{(126)}\)

The surfaces of adhesive tapes are much coarser than the surfaces of glue-lift disks and, therefore, make fewer contacts with the GSR deposits on hands. This is another reason why the tape-lift technique has failed to find the smallest GSRs (0.1 µm diameter or less) and to document these at high magnifications (Figure 3). The glue-lift has shown more discrete morphologies of GSR spheroids than all other attempts combined since GSR was first discerned both chemically\(^{(127)}\) and physically.\(^{(128)}\) Due to larger yields of GSR the glue-lift allows the search of GSR in a few marked circles (total area 7.1 mm\(^2\)). With the tape-lift, the entire 1-in or 0.5-in disk has to be searched for GSR. Statistical considerations do not provide sufficient justification for any significant reduction in the sample area of tape-lift to be searched.\(^{(129)}\) In summary, the advantages of glue-lift over tape-lift are smaller search time due to greater collection or yield of GSR; minimal pick-up of skin cells and other debris and hence cleaner collection; ability to lift GSR of a wide range of diameters (0.1–55 µm or above) and diversified condensed GSR morphologies; ability to avoid imbedment of GSR in the thin glue layer (a few micrometers thick); no need for coating the sample disks unless these have to be re-examined several months later; and a smaller search area (6%) of each disk to obtain adequate numbers of GSRs.

The SEM/EDX detection of GSR is also applicable to the determination of target distances.\(^{(110)}\) These studies involve examination of larger substrate areas than that of a specimen stub and so require automated or semiautomatic search techniques.\(^{(110,112,113)}\) The SEM/EDX analysis of GSR has confronted a new issue in recent years. The build-up of residual lead or GSR particles inside the barrel, the chambers, and the trigger housing of an unclean gun have the potential for carry-over of the deposited metals (Pb, Sb, Ba) to residues of lead-free\(^{(22,130–132)}\) and antimony-free\(^{(133)}\) primers. Environmental health problems associated with airborne lead particulates\(^{(134)}\) and acid-rain precursors (sulfates)\(^{(135)}\) may have generated a new awareness and have possibly tightened the production of lead- and antimony-containing primers. Therefore the development of new sampling procedures for GSR and explosive residues must continue.\(^{(136)}\) An important application of SEM/EDX for the medical examiner’s office is the detection and quantitation of GSR, bullet residues and bullet fragments in tissue scrapings collected from a bullet wound.\(^{(137)}\) The SEM/EDX has also determined that bone particles and bone-plus-bullet particles are a feature of backscatter from close-range shots to heads.\(^{(138)}\) The SEM/EDX has been used in combination with neutron activation analysis (NAA) to identify ammunitions used in a lethal robbery.\(^{(139)}\)

A routine undertaking of SEM/EDX is the inorganic elemental analysis of vehicular paint chips,\(^{(24,41,140–145)}\) glasses,\(^{(45)}\) ceramics,\(^{(63)}\) and bullets.\(^{(40,41,45,58,146)}\) Chemical markers obtained from the scenes of arson\(^{(61,147)}\) and theft,\(^{(148)}\) and dental alginate material\(^{(149)}\) have been identified with this technique. Traces of toxic elements (e.g. lead in regular gasoline, arsenic and mercury in contaminated food and ingested materials) are concentrated and the technique applied. The technique has produced evidence of a sulfur pump at the root of scalp hair and has been used for hair comparison based upon increased sulfur intensity along the length of a hair.\(^{(27,150)}\) The analysis of other biological inorganic elements such as sodium, phosphorus, potassium, and calcium in cross-sections of scalp hair has been used to compare hair.\(^{(151–153)}\) SEM/EDX has been applied to the examination of absorbed copper ions in human head hair.\(^{(27,154)}\) This technique is well-suited to examining papers\(^{(155)}\) and to identifying dynamite wrapping papers\(^{(156)}\) to solve forensic problems involving handwritten and printed documents,\(^{(157,158)}\) and inks.\(^{(158,159)}\) SEM/EDX has also been used to study the surface morphology and elemental
composition of the toner deposits on the copying papers and to identify the origins of questioned photocopied documents. 

Minute lipstick smears are sometimes found as evidence on clothing, cigarette butts, and other crime scene objects. SEM/EDX is able to differentiate these and to identify the manufacturer or brand name of lipsticks. The intrinsic ability of SEM/EDX to differentiate particulates based on their sizes and elemental make-ups has been used successfully to identify the origin of soil samples involved in an airplane crash.

4.4 Cathodoluminescence

CL is the emission of visible light under electron impact; it is akin to scintillation emission. The cascade theory suggests that several successive primary and secondary events follow after electron irradiation in organic compounds, which lead to primary $\pi$-electron excitation. The latter contributes to CL. Only a small proportion (10% or less) of the energy of incident electrons is expended in the excitation of $\pi$-electronic singlet states of unsubstituted aromatic hydrocarbons. The larger proportions of electron energy transfer is expended in ionizations and $\sigma$ transitions. De-excitation resulting from the primary excitations ($\pi$ and $\sigma$) create secondary luminescence excited by SEs, X-ray photons, ultraviolet and visible photons. All of these contribute to the final CL emission. The cross-section of CL is determined by the energy of the incident electrons and the target molecules, the generalized oscillator strength of which plays the central role in the processes of energy transfer. 

4.4.1 Detection Limits and Ranges

Two types of CL detection systems have been used to determine the detection limits and ranges of CL emission. These are the surface emissive detector and the transmitted (STEM) detector. The volume of sample involved in CL emission is much greater than that of SEs and BSEs. This volume generally approximates the total volume of primary electron diffusion. The STEM system is able to resolve structures up to 50 nm. The surface emissive detector offers a much poorer resolution (100 nm).

4.4.2 Applications

The CL studies of fluorochromes show that certain dye compounds such as fluorescein, thioflavine T, brilliant yellow 6G, and ethidium bromide are fairly electron resistant. They exhibit durable CL despite limited molecular damage by the incident electrons. Compounds such as acridine orange, 9-acridanone, and rhodamine-B are sensitive to electrons, and their CL emission is short-lived. Giemsa stain is a mixture of eosin-y, methylene blue, and azurs. This stain is not a fluorochrome but it shows intense CL up to 45 min after electron irradiation. The potent hallucinogenic drug LSD (lysergic acid diethylamide) is highly cathodoluminescent. The stimulant drug cocaine-HCl is less luminescent than LSD. Time-dependent studies of LSD incorporation into scalp hair show that CL studies of hair could possibly be utilized to determine the history of this drug abuse.

5 SCANNING ELECTRON MICROSCOPE SIGNAL PROCESSING AND APPLICATIONS

The imaging capabilities of SEM/EDX allow both compositional and topographical displays that can be readily interpreted. Illustrative evidence of this type is valuable in forensic comparisons. The ability of SEM/EDX to process each signal by various contrast enhancement methods allows an intuitive, stylistic, and synthetic analysis of the image. Forensic applications of three such methods are stressed in this section. These are X-ray dot mapping, line scanning, and DM or Y-modulation.

5.1 Dot Maps and Line Scans of Energy-dispersive X-rays

Conventional X-ray area scanning or dot mapping is similar to other kinds of SEM imaging – as the electron beam scans the specimen in raster mode, in synchronization with the CRT, the X-ray signal is detected by an EDS or WDS detector. The X-rays produce photoionizations in a liquid-nitrogen-cooled Si(Li) detector. A high voltage bias to the Si(Li) detector generates output pulses of collected electrons proportional to the X-ray energy. These pulses are integrated by a preamplifier, which is a field effect transistor (FET) and generates step signals. These signals are again amplified and given shapes of gaussian pulses by a linear amplifier. These pulses are processed sequentially by an analog-to-digital converter, a multichannel analyzer (MCA) for spectrum accumulation and storage, and a computer for data processing and display of the X-ray spectrum. The output of the analyzer is used to modulate the brightness of the CRT until dots appear on its display screen to specify the location of these X-ray emissions. By selecting an elemental X-ray peak and by adjusting an energy window of the MCA to two-thirds of half-band width of the peak, a dot map of that element is obtained. Compared to BSE and SE signals, the X-ray signals are weaker by a factor of $10^4$ – $10^6$; thus X-ray detection
takes much longer (a millisecond or more) than the detection of electrons (a nanosecond or less). A good practice is to subtract background X-rays and noise and to simultaneously enhance the image signal by using a digital filter before the X-ray signal is fed to the CRT, and then to generate an acceptable dot map by successive exposures at a scan rate of 2 min per frame. Operating conditions of the SEM are critically judged to avoid any significant drift in the dot map. Unless the X-ray signal is subtracted, detection limits in the analog dot mapping mode with EDS are 2–5% w/w, whereas for WDS, which has a greater peak to background ratio, the limit is about 0.5–1% w/w. Analog dot mapping is useful but it has artifacts as well as limitations. The long pulse-processing time of EDS leads to dead time effects, and these must be avoided. The dot maps are used for qualitative purposes, not for quantitative information. A large part of this problem results from the way the net scanning time is divided between x and y raster (i.e. scan) speeds. These scan speeds are determined by the x and y fixed resistors of the analog scan generator. In dot mapping in the raster mode, both speeds are equivalent. This often makes the dwelling time of the beam much shorter than in the detection of X-rays. The dots therefore appear sparsely and they are all of the same intensity. Therefore the area density of dots becomes dependent both on the density of the element in question and the geometry of the scanned area in a very complex manner that is not truly dependent on the specimen characteristics.

The chemical make-up of forensic substances can be deciphered by obtaining X-ray maps of the detected elements. The elemental maps are generally complementary to Z-contrast images of high-energy BSEs. Whether the spatial distributions of the detected elements are in successive layers (e.g. paint chips) or are highly discontinuous (i.e. heterogeneous), they can be determined by dot mapping. Despite the time involved, this technique is well-suited for the examination of documents and fingerprints of metallic inks.

The dot mapping technique has been applied to cross-sections of GSR to determine the formation processes of these particles during firearms discharge.

The dot maps are usually examined together with SE and BSE images of the physical evidence to obtain specific information of the constituents. An example is shown in Figure 13 using a hair formula (Grecian Formula®) as evidence. The hair formula was settled as a droplet on a polished carbon plancheted as described earlier in Figure 8. The SE image (Figure 13a) showed that the dried sediment contained a mixture of amorphous particles of various sizes, and spongy, thin, disk-like crystals in stacks. The EDX spectrum (Figure 13d) showed that the major elements (>10% w/w) of the mixture were sulfur, chlorine, and lead, with titanium as the minor (>1% w/w) element. The only heavy and toxic element detected was lead and so more information was necessary about this element. The Z-contrast BSE image in Figure 13(b) indicated that these could be the spongy, thin, disk-shaped crystals in the SE image (Figure 13a). Confirmation of this was achieved by dot mapping at the La peak of lead (Figure 13c) and/or by recording the X-ray spectrum of these crystals in the spot mode (Figure 13f). A lower magnification of the Z-contrast BSE image in Figure 13(e) showed that these Pb crystals are abundant in the hair formula. The X-ray peaks due to S(Kα), Pb(M), and Cl(Kα) are fairly close to each other and they affect each other by their own continuum. Therefore the Pb(M) line was not considered for the dot mapping of lead. These three elemental peaks are overblown in Figure 13(d) due to adjustment of the vertical scale of X-ray intensity (count rate). This adjustment was necessary in order to show that the Pb(La) peak was at or slightly above the two-sigma level (i.e. twice the background). Despite the fact that a digital filter was used to subtract the background, several dots due to the continuum are evident in Figure 13(c). Yet this dot map was preferably used for interpretation.

In analog line scanning the selected window signal is applied to an R–C (resistance–capacitance) ratemeter (e.g. EDAX®-352 module). The ratemeter output is applied to the vertical deflection (y) of the electron beam of the CRT. The x and y resistors of the analog scan generator are selected such that most of the scan time is spent on the x speed and very little on the y speed. The result is a single-line scan along x. Because the y scan is much faster than the x scan, the fast change in count rate produced by the y scan creates R–C distortions. These are due to the lack of correspondence between the time constant of the R–C circuit of the ratemeter, count rate, and scan speed. The major problem is tailing or the masking of changes when the time constant for the R–C circuit is too high. The other problem is due to the high count rate (the dead time effect) when the signal reaches an immediate saturation instead of rising or decreasing in proportion with the count rate. These and other problems of analog line scans are minimized by proper combinations of count rate, slower scan speed, and ratemeter settings (scale factors for integration). Furthermore, the ratemeter allows smoothing of the line-scanning signal, which removes noise due to fluctuation in background counts.

The line scanning technique has the inherent ability to produce useful parameters for comparative hair identification. As sulfur (S) is the major (6% w/w) inorganic element of hair keratin, both perpendicular and longitudinal line scans of S (Kα) serve as a reference for determining the modes of distribution of other elements in hair. An SE image of the sample area is
Figure 13 A hair liquid (Grecian Formula®) settled as a droplet on a polished carbon planchet: (a) SE image of the dried sediment, magnification 500×; bar 20 µm; (b) Z-contrast BSE image, magnification 500×; bar 20 µm; (c) dot map at Lα peak of detected lead, magnification 500×; bar 20 µm; (d) EDX spectrum showing major (>10% w/w) elements, namely sulfur, chlorine, and lead, and the minor (>1%) element titanium; (e) lower magnification (200×) of the Z-contrast BSE image in (a), bar 50 µm; (f) X-ray spectrum of the disk-shaped crystals in (a), 20 kV.
superimposed over the elemental line scans (Figure 14). These line scans are marginally affected by the continuum if other elements (phosphorus, chlorine, etc.) are absent from the area of examination. An important parameter of hair identification is offered by a sudden rise in the uptake of sulfur within the endoderm portion of the root of hair, which is followed by a gradual increase in sulfur concentration along the hair shaft. The rate of incorporation of sulfur at the root of a hair (the sulfur index) varies remarkably from one individual to another.\(^{27,150}\) This information has been confirmed by measuring the count rates in the spot mode at the roots of hairs, and then along the length of both anagen and telogen hairs of many individuals (Figure 15).\(^{150}\)

### 5.2 Deflection Modulation Imaging with Energy-dispersive X-rays

A novel technique for precisional identification of trace evidence using SEM/EDX is by DM of elemental X-ray signals to generate multiple line scans.\(^{168}\) This technique requires a potentiometer to vary the \(x\) speed while the \(y\) speed (i.e. its resistor) remains fixed. This generates numerous line scans per frame (e.g. 48–100, 110–375, etc.). The X-ray continuum and noise in the image are removed by a threshold setting to the count rate. The threshold setting is achieved by a negative voltage shift of the brightness potentiometer of the CRT on the SEM panel. The recording time as determined mostly by the \(y\) speed is 3 min 40 s for each elemental image.\(^{168}\)

This image processing technique accentuates both concentration-dependent and topography-dependent intensity variations. The surface topography selects one or the other. The concentration dependence of the X-ray intensity predominates on smooth flat surfaces, whereas with irregular objects or surfaces, the intensity variations are topography-dependent. These pseudotopographic images of elements are like fingerprints of element distribution in three dimensions in the object. Figure 16 is the lead image of a GSR particle. These particles form by condensation from a state of vapors. The technique offers a nondestructive test for such cases.\(^{168}\) The concentration-dependent images are able to identify scraping and scratching in violent attacks (e.g. on a watch, watch band, rings, etc.). This technique has generated illustrative evidence of the sulfur index which is characterized by a sudden rise in the intensity of sulfur a short distance away from the root of head hair.\(^{169}\) This technique is undoubtedly superior to dot mapping\(^{169}\) and has the potential to solve difficult cases of toolmarks where these are faint or have been obliterated (e.g. firing pin impressions of shotguns and rifles).

### 5.3 Deflection Modulation Imaging with Secondary Electrons and Backscattered Electrons

The image processing in the SEM by DM allows augmentation of depths and topographic features. DM also recovers some of the flaws which are suppressed in the original SEM signal. A critical evaluation of this method, in comparison with the SE and BSE imaging methods, has been made elsewhere.\(^{24}\) This technique is suitable for sequencing of intersecting lines of pencils and ball-point pens which produce relatively deep and equal impressions on the paper.\(^{24}\) The technique has been used to identify individual characteristics of the firing pin impressions of shotguns.\(^{24}\)

### 6 FORENSIC AND ENVIRONMENTAL REGULATIONS, METHODS, AND LAWS

#### 6.1 History of the Scanning Electron Microscope and Energy-dispersive X-ray Microanalysis in Court

In admitting GSR evidence examined by SEM/EDX in People v. Palmer (1978),\(^{170}\) the court in California for the first time noted that the SEM/EDX technique had been uniformly accepted by the scientific community. The accused’s objection as to the reliability of the technique was rejected. With the recognition of the potential of the SEM/EDX technique, efforts to overcome its limitations and to improve its credibility have continued. In 1980, in
Figure 15 Plots of background-free X-ray intensity (Is) of sulfur (S) versus distance measured from the proximal (root) end of an individual’s hair. The count rate was measured in the spot mode at the root of hair and then along length of both anagen (ANA) and telogen (TELO) hair. The rate of incorporation of sulfur at the root of hair (the sulfur index) is almost invariable for different hair of a particular individual (see insert on left) but varies significantly from one individual to another.\(^{150}\)
Figure 16 DM image of lead in a GSR particle. Multiple line scans are due to Pb(M) X-rays.\(^{(168)}\) (Magnification 10,000\( \times \); bar 1\( \mu \)m; 20 kV.)

People v. Jean Harris, the court of West Chester County, New York, admitted the elemental analysis of bullets and bullet fragments using the SEM/EDX. GSR analysis with the glue-lift has been admitted into evidence by various courts in the state of New York in many cases since 1981, including People v. Patricia Thrush, People v. D.K. Ventiquattro, and D. & T. Wronka’s v. Trooper R. Galarza.

6.2 Daubert (1993) v. Frye (1923) Rules

The general acceptance principle, which serves as a criterion for the judicial admissibility of scientific evidence, was set forth on 3 December 1923, by the Court of Appeals of the District of Columbia in the case of Frye v. United States.\(^{(171)}\) The trial court had sustained the prosecutor’s objection to the admission of lie detector (polygraph) evidence. The appellate court set forth the general acceptance standards by saying that it is difficult to define just when a scientific principle or discovery has crossed the line between the experimental and demonstrable stages. “Somewhere in this twilight zone the evidential force of the principle must be recognized, and while the courts will go a long way in admitting expert testimony deduced from a well-recognized scientific principle or discovery, the thing from which the deduction is made must be sufficiently established to have gained general acceptance in the particular field in which it belongs.” This Frye rule has been debated in recent years for three reasons. The rule has no safeguard to justify the quality of expert witnesses who may be using the same principle and technique but a variant of methodologies of their own. The rule does not oversee if the scientists openly discuss the pros and cons of accepted practices and the veracity of claims which are unnoticed by the court. The rule enforces a clinging of scientists to accepted principles, barring the entry of new and novel principles which as a matter of fact do not gain widespread support within the scientific community.

In 1993, in a landmark ruling in Daubert v. Merrell Dow Pharmaceutical, Inc.,\(^{(172)}\) the US Supreme Court took a different view about the Frye rule by asserting that this rule is not an absolute prerequisite to the admissibility of scientific evidence under the Federal Rules of Evidence.\(^{(173)}\) The Court observed that according to Federal Rule 702 (Testimony by Experts) trial judges hold the ultimate responsibility for the admissibility and validity of scientific evidence presented in their courts.

6.3 Federal Rule of Evidence 702 and Expert Witness

Rule 702 defines expert testimony. Under this rule a witness may be an expert by virtue of “knowledge, skill, experience, training or education”. If they are thus an expert, they may testify to “scientific, technical, or other specialized knowledge” in their area, but only if it will “assist the trier of fact to understand the evidence or determine a fact in issue”.\(^{(173)}\) Daubert\(^{(172)}\) has put the science and technology where they should be. Using the Federal Rule 702 as a perspective this rule has added credibility to reliability standard of Frye.\(^{(171)}\) In fact the court in Daubert\(^{(172)}\) has given several guidelines for a judge to qualify an expert witness and the scientific evidence, e.g. whether the technique or theory has been tested and can be tested, whether these have been peer reviewed and published, what the limitations are and the potential rate of error of the technique, whether standards exist and were maintained to control the technique’s operation, and whether the theory or method has received widespread acceptance within a particular field in which it belongs. Forensic experts must notice that these legal guidelines set the stage for the subsequent sections of this review.

6.4 Environmental Monitoring and Scope

The users of the SEM must be aware of environmental and occupational hazards associated with the equipment and reagents in the SEM laboratory. They must know the laws and follow proper procedures in all hazardous situations to dispose of dangerous wastes. The environmental laws of using various chemicals and the equipment must be discussed in a training course so that students and trainees can make informed choices of their lines of research. The objective is to protect the environmental health and the associated quality of living. Routine environmental monitoring of the SEM laboratory must cover (1) personal safety and first aid kits, (2) chemical safety as
per OSHA (Occupational Safety and Health Administration (US)) standards, (3) fire safety, (4) electrical safety, (5) physical and mechanical hazards associated with equipment and accessories and consumables, including compressed gas and liquid cylinders, (6) training and orientation programs, and (7) hot lines.\(^\text{[12]}\) Some of the hot lines (telephone numbers) to be kept in the laboratory are Environmental Protection Agency (wastes 800-424-8802; toxins 800-424-9065), National Institute of Occupational Health and Safety (800-356-4674), Consumer Product Safety Commission (800-638-2772), American Chemical Society – Health and Safety Referral Service (202-872-4511), Chemical Transportation Emergency Center (800-424-9300), and Chemical Manufacturers Association (800-262-8200).

On 31 January 1990 the OSHA published a set of rules in the Federal Register for dealing with dangerous chemicals in the workplace. This standard is entitled *Occupational Exposures to Hazardous Chemicals in Laboratories*, and it must be complied with by all science laboratories in the USA. This standard enforces a *Chemical Hygiene Plan* for each laboratory. According to this plan the laboratory must develop a set of *Standard Operating Procedures* that cover general safety precautions while using chemical exposure control measures (fume hoods, respirators, gloves, goggles, etc.), spill control measures, accident responses, and disposal methods to follow upon completion of the procedure. A safety officer must be designated and the employer is required to provide training on the *Chemical Hygiene Plan*. The OSHA standard also applies to gases, vapors, and aerosols created in the laboratory. As the SEM has to run all year in many laboratories, its mechanical pumps must have exhausts through the laboratory into the open air.

### 6.5 Monitoring of Radiation Hazards

Commercial SEMs are usually well shielded against X-ray leakage, but a new SEM must always be checked for leakage with a Geiger counter for beta and gamma radiation. Leakage greater than 0.5 mR h\(^{-1}\) measured at 5 cm from the SEM column is considered significantly hazardous by the Electron Microscopy Society of America (currently Microscopy Society of America) Radiation Committee of 1973. The SEM should be monitored periodically for leakage of X-rays by operating it at the highest voltage with apertures slightly out of alignment and the beam expanded. A well-shielded SEM will register zero counts above the background (25 counts per second) due to cosmic rays. Obviously each operator of the SEM must bear a radiation badge (X-ray film), and these badges must be developed and monitored periodically by an external radiation detection/monitoring service provider.

### 6.6 Survey of Methods

Just as a regular safety inspection is necessary in order to assure compliance with established rules and to stop negligence before an accident occurs, the surveying of methods used in the SEM laboratory is important as it can save reputations and the cost of litigation. An example of this is the CPD method. The CPD apparatus is often called a bomb because extreme pressures build up inside these units during the drying of biological evidence. The apparatus must be well shielded. Accidents happened with some commercial CPD units in the late 1970s. There are several alternative protocols of CPD that produce the same results, and the overwhelming consensus has shown that the best method is using liquid CO\(_2\).

## 7 QUALITY CONTROL, STANDARDS AND SOURCES OF ERROR OR TROUBLESHOOTING

### 7.1 Data Quality Objectives

It is fair to assume that most SEM laboratories have their own priorities or goals. The priority of forensic science laboratories is to generate casework, whereas the priority of a manufacturer’s laboratory is to make quality products. These priorities are different due to different strategies. The priorities require implementation of objectives as these can be achieved, measured and evaluated with respect to standards. Fortunately, the SEM is a versatile instrument and is able to meet the demands of quantity and quality. An example of this is elemental analysis. The SEM analyst of a crime laboratory can generate casework by analyzing each item of evidence in the spot mode. This method is considered as reliable as, and much faster than, the image processing methods using dot mapping, line scanning, DM, etc. The SEM analyst in the manufacturer’s laboratory, however, will try these contrast enhancement methods to show the quality of a product. The thing that is expected of these two SEM analysts is that each has used a set of controlled operating procedures to secure data, and that such data are evaluated on a routine basis using standard materials. In the words of Daubert\(^\text{[172]}\) these data can, therefore, be tested. These objectives which assure quality of data are called data quality objectives. These specific and measurable objectives of the quality of the product or service by an analytical laboratory are the foundation on which the International Organization for Standardization (ISO) 9000 program is built.\(^\text{[174]}\)
7.2 American Society for Testing Materials E-30/National Institute of Standards and Technology Standards

Founded in 1898 and currently headquartered at West Conshohocken, Pennsylvania, the American Society for Testing and Materials (ASTM) has for a century been in the forefront of developing consensus standards.\(^{(175)}\) The ASTM standards began with A-1 on steel, stainless steel, and related alloys in 1898 under the initiative of Dr Charles Dudley. The ASTM standard E-30 on forensic science was developed in 1970. The ASTM committee E-30 began actively formulating standards for laboratory procedures and standard practices after a reorganization meeting. This meeting took place in Las Vegas in 1989 in association with the Annual Meeting of the American Academy of Forensic Sciences. Twenty voluntary consensus standards were adopted,\(^{(176)}\) including E1588-95 Standard Guide for Gunshot Residue Analysis by Scanning Electron Microscopy/Energy-Dispersive Spectroscopy. Developed by ASTM subcommittee E30.01,\(^{(177)}\) this guide covers the analysis of GSR by SEM/EDS. The analysis may be performed manually, with the operator manipulating the microscope stage controls and the EDS system software, or in an automated fashion, where some amount of the analysis is controlled by preset software functions requiring little or no operator intervention. As software and hardware formats vary among commercial systems, guidelines were offered in general terms. Three NIST/NIH (National Institutes of Health) softwares for image analysis and microanalysis can serve both as practical tools for solving problems in the SEM/EDX laboratory as well as standards for microanalysts at all levels of experience. These softwares are NIH Image,\(^{(178)}\) MacLispix,\(^{(179)}\) and NIST Micro MC.\(^{(180)}\) These softwares, as well as Desktop Spectrum Analyzer (DTSA) of Chuck Fiori, Carol Swyt-Thomas and Bob Myklebust, are freeware available from a source (CW11) of NIST (http://micro.nist.gov/dtsa/dtsa.html).

7.3 Monitoring of Vibration and Stray Magnetic Fields

Two environmental barriers to high-resolution imaging are mechanical vibration and alternating magnetic field interference. These must be minimal at the time of installation of the SEM and are monitored periodically. The probe size increases drastically with these barriers. Low-frequency vibrations (2–10 Hz) are due to natural vibrations of the building. Motors are sources of a large range of frequencies. Commercial SEM equipment usually comes with an antivibration table under the microscope column. Power supplies (60 Hz or higher) are major sources of stray magnetic fields. The electron beam at low voltages is particularly sensitive to oscillating stray magnetic fields.

7.4 Control or Elimination of Charging Effects

When an electron beam impinges on the specimen, a large proportion of electrons remains in the specimen as they lose all of their initial energy. If the specimen is a conductor and the specimen stage is grounded, this charge flows to ground. If the ground path is disconnected, even the conducting specimen quickly accumulates charge and can deflect the scanning beam off the specimen. Charging is frequently encountered with insulators or specimens containing insulating materials. Charging manifests itself in images in a variety of ways.\(^{(5)}\) Nonconducting specimens invariably need coating and conductivity techniques before they can be examined.\(^{(5)}\)

7.5 Control or Elimination of the Sources of Spurious X-rays

The brass surfaces of solid-state backscatter detector systems are the main sources of spurious X-rays due to copper and zinc. After removal of this system from the SEM, the solar windows and their leads to a chain of amplifiers are carefully covered with small circular pieces of masking tape. The system is then coated with carbon (thickness > 10 µm) by several cycles of carbon evaporation in a vacuum evaporator. The masking tape is removed and the system reinstalled. The collimator window of the X-ray detector (EDS) is also coated with thick evaporated carbon. This avoids spurious X-rays due to aluminum. Commercial-grade carbon paints and inks contain ferromagnetic elements (iron and cobalt). These are not suitable for carbon coating. BSEs reaching those surfaces from the specimen mount are completely absorbed by the thick carbon coating and are not able to produce the spurious X-rays.\(^{(27)}\)

7.6 Control of Instrument Performance and Detector Geometry

The control of SEM operating conditions and their optimizations are discussed in sections 4.1.1, 4.2.1, and 4.3.1. The SEM images of cavities, grooves, lines, line-crossings, and faceted objects suffer from shadow effects depending upon the shape and orientation, toward or away from the SE detector. These and other effects of image contrast due to SE detector geometry have been studied elsewhere.\(^{(24)}\)

8 COMPARISON WITH OTHER MICROBEAM ANALYTICAL METHODS

8.1 Comparison of Technology

The SEM’s ability to generate easily interpretable images of surface topography, crystallography, and material
composition, and the ability to process each specimen
signal by various contrast enhancement methods that
allow an intuitive, stylistic, and synthetic analysis of the
image, has made the SEM one of the most versatile
instruments available for microstructural examination
and analysis of physical evidence.

Today, it is estimated that well over half of all SEMs
are now equipped with X-ray analytical capabilities.\(^{(5)}\)
In trace evidence analysis involving the examination
of GSR, hair, fiber, etc., physical matching and non-
destructive elemental analysis of physical evidence, the
SEM/EDX is the most efficient of all microbeam tech-
nologies. No other microbeam technology combines
high resolution with large depth of field for three-
dimensional viewing and then allows image processing.
The SEM is indeed a research tool in industry and
academia.

The digital SEM, or the SEM coupled to a computer
to provide a digital signal, now has the capability
to process images stored on a magnetic disk and to
generate all the desirable effects achievable by the older
analog SEM. These systems have allowed automated and
unattended search and analysis of forensic, occupational
and environmental particulates.\(^{(17,110,112,117–121,134)}\) The
current imaging trend is to record all data digitally. The
advantages of digital acquisition are instant viewing and
recording, immediate interpretation and quantification,
fast distribution, and storage for further analysis. Digital
image processing has affected all microbeam technologies
including the SEM. In this regard the SEM is both
competitive with, and complementary to, the capabilities
of other microbeam technologies.

In the analysis of elemental composition, the SEM’s
counterparts are the EPMA, Auger electron spectroscopy
(AES), and X-ray fluorescence (XRF). In the EPMA the
primary radiation of interest is the characteristic X-rays
produced by electron bombardment. The microprobes
in combination with WDS allow both qualitative and
quantitative compositional information from areas of a
specimen as small as a micrometer in diameter. Both
EPMA and AES have the benefit of superior lateral
resolution of elements over EDX. Also, with AES,
elements of low mass number (carbon, nitrogen, oxygen,
etc.) and elements whose X-ray peaks overlap with
the EDX can be quantified. When AES is used in combination
with sputtering equipment, depth profiles of the elements
can be obtained.\(^{(181)}\) XRF is used in forensic laboratories
to detect the presence of a wide range of elements present
at concentrations of about 10\(\mu g\) g\(^{-1}\) or greater in trace
evidence. The concentrations of most elements needed for
characterization of source of trace evidence by SEM/EDX
are too low to be detectable.\(^{(182)}\) The SEM/EDX is not
ideal for quantitative analysis of elements present as
traces (<1% w/w).

The SEM is more suitable for examining irregular
objects than the scanning tunneling microscope (STM),
or the atomic force microscope (AFM). In the STM
and AFM the probe interactions become difficult to
control and understand when irregular or multiple sur-
faces are involved. The capabilities of STM and AFM
are most utilized with flat surface-like membranes.\(^{(183)}\)
Some of the best modern SEMs now have spatial res-
olutions in the nanometer range. These are fairly close
to resolutions achieved with a TEM. The SEM lacks
the three-dimensional sectioning abilities of scanning
beam confocal microscopes. However, the analytical
capabilities of the SEM cannot be matched by light
microscopes because the resolution is far superior.
The principles of image formation and image pro-
cessing in the SEM are well understood. The SEM
is, therefore, a major tool in forensic research and
investigation.

ACKNOWLEDGMENTS

Thanks are due to New York State Police Crime Lab-
oratory for implementing the NYSP GSR Program using
the glue-lift technique during 1980–89. The participation
of many officers from all troops of the New York State
Police in the GSR program is thankfully acknowledged.

1 INTRODUCTION

XRF techniques are based upon the emission of characteristic X-rays from the elements in the sample due to their excitation by absorption of a primary beam of X-rays. These techniques can perform rapid and nondestructive qualitative multielemental analyses of barely visible samples, which constitutes a major advantage in a forensic context. Modern XRF instruments can also produce quantitative analyses of complex materials. However, most XRF techniques are not as sensitive as other methods, such as inductively coupled plasma mass spectrometry (ICP/MS), for example.

This article discusses the application of XRF techniques in forensic science, including limitations and practical aspects. For completeness, electron probe microanalysis (EPMA) or scanning electron microscopy/energy-dispersive X-ray spectrometry (SEM/EDX) is also considered, although in this case the X-ray spectrum is induced by an absorption of electrons instead of a primary beam of X-rays.

2 ELEMENTAL ANALYSIS AND X-RAY FLUORESCENCE IN FORENSIC PROTOCOLS

Most forensic examinations deal with the identification of a sample, the comparison of samples coming from different sources, and the interpretation of the results obtained in the context of the events. Forensic science is largely based on a comparison process. The aim of this process is to attain the highest degree of discrimination between very similar samples. In a particular case, choosing appropriate techniques from the wide range available will depend on several factors including the nature (primarily organic versus inorganic matrix) and the form of the sample, the quantity of material available, the exact circumstances of the case under investigation, and the instrumental techniques available to the laboratory. It is good forensic practice to follow a stepwise progression from simple, general, rapid, widely applicable, and nondestructive screening methods to more discriminating, specific and sometimes destructive methods. The comparison process considers morphological, physical and chemical characteristics. In modern forensic laboratories these characteristics are largely determined by microscopic examinations, color/dye characterization using microspectrophotometry and/or chromatography (thin-layer chromatography or high-performance liquid chromatography), and other instrumental techniques. In this context, it becomes obvious that techniques yielding elemental information are generally only used during
the later stages of a forensic examination. In addition, in some cases there might be no need for an elemental analysis because enough discriminative information has been obtained by simpler tests.

Nevertheless, in many cases it may be important to characterize the sample not only in terms of the organic matrix, but also in terms of the elemental profile. The elemental analysis is obvious for samples which are in essence inorganic, such as metals and glass, or for samples with a significant inorganic content, such as GSR, soil, or paint containing inorganic pigments. This type of analysis can also be useful to compare samples which are in essence organic, such as plastics/general polymers or fibers on the basis of their trace element profile. In some cases, this information can lead to samples being differentiated which would have remained otherwise indistinguishable.

XRF techniques can be used whenever there is a need for elemental profile characterization. The main advantage of these methods over other elemental techniques such as atomic absorption spectrometry (AAS) or ICP/MS is their nondestructive nature, which is a highly desirable feature in forensic science. The ability of these methods to analyze small solid samples with accuracy, precision and speed constitutes another advantage in the forensic context. The spectra are also relatively simple to interpret. Disadvantages include a relatively mediocre sensitivity (in the ppm range in the best cases), inconveniences associated with quantitative analyses, and difficulties in detecting and measuring light elements.

3 TECHNOLOGY

The common XRF techniques used in forensic science include:

- conventional XRF spectrometry;
- EPMA (also known as SEM/EDX or scanning electron microscope (SEM)/EDS);
- X-ray fluorescence microanalysis (XRFM or micro-XRF);
- total reflection X-ray fluorescence spectrometry (TXRF).

Key factors to consider when determining which technique will best serve the analytical needs of the forensic scientist include:

- What is the sample size and/or feature size to be analyzed?
- What elemental sensitivity and/or compositional variations need to be resolved?
- What degree of sample preparation is acceptable or required?
- What analytical environment is acceptable: air, helium, or vacuum?
- What are typical sample sizes and manipulation requirements?
- Is the sample physically and chemically sensitive to beam damage and/or contamination?
- What is the sample analysis turnaround time?
- Is automation important?

Due to the size of typical forensic samples, and the need for nondestructive analyses, the forensic scientist will generally favor techniques with a good spatial resolution, and those which minimize sample preparation. In some cases, automation and/or elemental sensitivity can also be key features. In summary, an ideal XRF technique for forensic applications should combine good spatial resolution, elemental sensitivity, easy sample preparation, and automation capabilities.

3.1 Conventional X-ray Fluorescence Spectrometry

Conventional XRF has good elemental sensitivity and is widely used for the qualitative analysis of elements with an atomic number greater than oxygen (i.e. >8). It can also be used for semiquantitative or quantitative analyses. Two types of spectrometers exist, wavelength-dispersive and energy-dispersive instruments. In the first case, the separation of the polychromatic XRF is achieved by dispersion through a rotating crystal, whereas in the latter the different energies composing the spectrum are separated by a multichannel pulse-height analyzer. It is beyond the scope of this article to discuss in detail the difference between the two systems. Suffice to say that energy-dispersive spectrometers are best suited to forensic applications because of their increased sensitivity and their improved signal-to-noise ratio.

The sample can be analyzed in various forms including solids, powders, evaporated films, and solutions. This renders conventional XRF suitable for analyzing a range of forensic samples (e.g. pieces of metal, large glass fragments, soil samples, etc.). However, conventional XRF is a macroscopic technique, and does not have good spatial resolution. It is therefore not applicable to the analysis of minute samples often encountered in forensic casework, such as fibers or glass fragments. As a result, forensic scientists generally prefer to use one of the specialized techniques described below.

3.2 Electron Probe Microanalysis

EPMA differs from the other techniques described in this article in terms of the type of interaction inducing the X-ray spectrum. In EPMA, the X-rays characteristic of the specimen are induced by a beam of electrons instead of primary X-rays. In the forensic context, the
primary advantage of EPMA is its strong link with the imaging of the SEM. Coupled with the SEM, and thanks to its excellent spatial resolution (of the order of 1 µm), this technique can characterize minute particles by observing the morphology and size of the particle in addition to carrying out the elemental analysis on a specific area of the specimen. For example, it can be used for the analysis of a microscopic glass bead deposited on a headlight filament, or a single gunshot residue particle. Compositional mapping showing the elemental distribution in the area of interest is also possible, which can have some application in the analysis of automotive paints, for example.

However, the relatively poor sensitivity of EPMA due to the high X-ray continuum background (Bremsstrahlung) precludes its use for trace element characterization, such as the minor elements contained in a single textile fiber or in general polymers. In addition, nonconducting samples require coating. The analysis also requires high vacuum and therefore is not well suited for liquids, volatile or biological samples. Despite these limitations, EPMA is often encountered in forensic laboratories because it constitutes the standard technique for GSR analysis. It is useful for the analysis of any forensic sample where the need for good spatial resolution outweighs the need for high elemental sensitivity.

3.3 X-ray Fluorescence Microanalysis

This combines the excellent elemental sensitivity of conventional XRF with spatial resolution in the EPMA range. A typical XRFM system is equipped with a collimated microfocus X-ray tube, a rhodium anode, an optical sample viewing/positioning device, and a precision computer controlled xyz stage. With XRFM it is possible to scan, locate, and analyze particles of 10 µm and larger (up to some 20 cm in diameter). Multiple-point microfluorescence analyses are also possible and can provide an average composition and information on elemental heterogeneity. Elemental maps can indicate the distribution of elements of interest across the sample, which can show the distribution of GSR around a bullet entry hole or the distribution of inorganic pigments on a surface coating. Multielemental analyses are possible from sodium to uranium in a rapid and nondestructive manner. The sensitivity is 100–1000 times better than that of EPMA, and the sample preparation is much simpler (no coating is required). Heavier elements can be analyzed at atmospheric pressure, whereas lighter elements can be analyzed under helium or at reduced pressure. Samples such as pastes, solutions, and volatile liquids that cannot be analyzed by EPMA (due to the requirement to work in a vacuum) can be readily analyzed by XRFM, making it a technique of choice for the elemental analysis of a wide range of forensic samples thanks to the features indicated above.

Unfortunately, most XRFM systems are not able to analyze particles less than 10 µm because the performance is restricted by the size of the collimator (minimum 50 µm) and the power of the X-ray tube (maximum 100 W). The smaller the collimator, the less energy hits the sample, and the less signal is detected.

A new type of XRFM has been recently developed with an emphasis on forensic applications. A novel approach has been employed, using capillary optics to guide and compress X-rays to very intense beams with a small angular dispersion. The two key features of good spatial resolution and high elemental sensitivity are obtained by this approach. This technology is claimed to be able to analyze particles as small as 5 µm in diameter. In some cases this improved spatial resolution may be significant. Otherwise, the capabilities of such a system are not significantly different from those of a more traditional XRFM system.

3.4 Total Reflection X-ray Fluorescence Spectrometry

This technique differs from conventional dispersive energy XRF in that the incident X-rays arrive near the critical angle of reflection without penetration into the sample substrate. The sensitivity is greatly improved (in the picogram range) thanks to a better signal-to-noise ratio. Another advantage of the technique is its ability to perform quantitation using a single element internal standard. The TXRF method appears to combine the much needed requirements of high sensitivity and the ability to analyze minute solid samples. The current price for such a system is rather prohibitive for routine analyses (in the order of US$250,000). Only a few studies have been reported on forensic applications (see below); however, TXRF is already seen as an excellent method for characterizing the trace element profiles of minute samples, including specimens that are essentially organic in nature (such as plastic wraps, synthetic fibers, etc.).

4 FORENSIC APPLICATIONS

4.1 Metals

In forensic science it is sometimes important to analyze metals such as debris from projectiles, metal filings, or other metallic exhibits relevant to a case under investigation. The choice of the technique is dependant on the size of the sample and on the resources available to the forensic laboratory.

If the sample is macroscopic, e.g. a metal plate, it can be analyzed by conventional XRF with no major
problem. If the sample is microscopic in size, EPMA or XRFM becomes the method of choice. The first is chosen for single-particle analyses when elemental sensitivity is not an issue. The latter is more appropriate when good sensitivity and/or elemental mapping is required. For example, with XRFM, it is possible to identify the position and composition of microscopic metal particles originating from a bullet on cloth, skin, etc., without removing the particles and with limited sample preparation.\(^{(2,3)}\)

### 4.2 Gunshot Residues

Most of the techniques available for detecting GSR on a suspect’s hands or clothing are based on the inorganic primer components of the ammunition. In the past, GSR analysis has been carried out using a number of different bulk elemental analysis techniques including neutron activation analysis (NAA), AAS, and inductively coupled plasma (ICP) techniques. Currently, the standard technique is EPMA.\(^{(4,5)}\) An adhesive SEM stub is repeatedly pressed over the area of interest (for example, the hands of a suspect). The stub is then analyzed by EPMA. The advantage of EPMA over the bulk elemental analysis techniques is that it is a nondestructive method that characterizes individual GSR particles by morphology and size, in addition to carrying out the elemental analysis. Generally, GSR particles are spherical and between 0.5 and 5.0 µm in diameter, although particles of over 100 µm have been observed.\(^{(6)}\) Also, whereas the bulk elemental analysis techniques only allow a total quantity of each of the elements to be given, with EPMA it is possible to determine whether each of the elements observed are present in a single particle. As each of these requirements are filled, it becomes more likely that the particle in question is in fact GSR, and not an environmental contaminant.

The main disadvantage of EPMA is that it is time-consuming and particles may be overlooked. This problem has been somewhat overcome by the introduction of automated instrumentation.\(^{(7–9)}\)

The potential of XRFM as an alternative to EPMA for gunshot residue analysis has been recently reported.\(^{(3,10)}\) Although this technique is ineffective at analyzing individual particles that are less than 10 µm in diameter, it shows interesting features. The elemental mapping capabilities can be used for the on-target analysis of the dispersion of GSR around bullet holes. The analysis of residues on target substrates can potentially indicate the type of primer employed (lead based or lead free) and the nature of the projectile (for example, fully jacketed or exposed lead). An indication of the muzzle-to-target distance (for example, less than 30 cm, or more than 30 cm) can also be obtained from this analysis. As this procedure is nondestructive, it does not preclude the application of more conventional techniques. An example XRFM

![Example XRFM spectrum of GSR from Winchester 9 mm NATO ammunition.](image-url)
spectrum of GSR is shown in Figure 1. An example of on-target elemental mapping by XRFM for the analysis of GSR dispersion is shown in Figure 2.

It should be pointed out that a number of manufacturers have recently developed new types of ammunition which are lead or heavy metal free. The main inorganic constituents of GSR derived from this ammunition type are not specific to gunshot residue, and may be present as an environmental contamination. This means that the applicability of EPMA or XRFM, like other inorganic techniques, to the detection of these types of GSR is limited. As a result, these techniques may be less useful in the future, and the forensic examination of GSR may swing towards the organic analysis of propellant residues.

4.3 Paint

Paint is a typical example of trace evidence, and is routinely analyzed by forensic laboratories around the world. The analysis of paint smears or paint flakes can provide crucial information in linking two items, or an item with a person. Common examples include motor vehicle accidents and burglaries, e.g. contact between a painted tool and a window frame. Forensic paint examination protocols include elemental profile characterization, in addition to optical examination and organic analysis. Elemental analysis targets inorganic pigments and extenders present in the paint sample.

The application of XRF techniques to forensic paint analysis is well established and has been reported by many authors. It has been shown that automotive paint samples coming from different makes and models are easily differentiated using XRF. However, samples coming from different locations from the same vehicle may also show some differences. When dealing with automotive paints it is therefore important to collect appropriate samples in terms of number of samples and sampling locations on the car.

Recent studies have shown that XRFM is particularly useful with such small solid samples and provides a better discrimination than X-ray diffraction measurements. The mapping capabilities of XRFM are of particular interest as well.

4.4 Glass and Soil

When glass is examined in forensic science, the most common analysis performed is the refractive index (RI) determination. Nowadays this can be quickly and easily achieved even with microscopic fragments using a glass refractive index measurement (GRIM) automated system (Foster and Freeman, UK). However, in some cases it may be important to characterize the elemental composition of the glass. The elemental composition has the potential to further discriminate similar glass fragments which remain indistinguishable on the basis of their RI. The elemental composition can also indicate the end-use category of the glass being examined (i.e. container glass, headlamp, window, etc.). An understanding of the distribution of the elemental composition within and between glass sources undoubtedly enhances the interpretation of this type of evidence. The elements of interest include Al, Fe, Mg, Mn, Sr, Zr, Ca, Ba, Ti, Rb, Sb, Pb, Na, and K. Several techniques can be applied to obtain elemental composition information on forensic glass samples.
However, due to the nature of the material, solid-state techniques such as XRF are often preferred. In addition, as glass is often encountered as submillimeter particles, micro techniques are best suited (i.e. EPMA or XRFM). The EPMA method can be used for the in situ characterization of very small samples such as glass beads on headlight filament, and has a better sensitivity than XRFM for lighter elements. The method of choice is probably XRFM because it requires little sample preparation and has a better sensitivity than EPMA for elements heavier than Ca. For the analysis, a submillimeter sample can be stuck onto a piece of clear sticky tape, or glued on a thread of cotton.

In forensic science, soil can be useful for linking the suspect or a victim to a scene, or an object to a scene. A typical protocol for forensic soil analysis includes pH and color determination, particle size distribution, particle density distribution, and some kind of instrumental analysis, possibly including XRF. For example, Hiraoka could classify 110 soil samples into nine categories using their element profiles based on Si, K, Ca, Ti, Fe, Rb, and Sr. These categories showed good agreement with known geological features. Although the potential of XRF for soil analysis has been demonstrated, it is fair to say that it does not constitute a routine technique for soil analysis.

4.5 Fibers

Fibers are generally examined using a protocol with a large emphasis on microscopic techniques. In addition, fibers are commonly analyzed using visible microspectrophotometry and Fourier transform infrared microspectroscopy. Elemental analysis is rarely carried out, but can supplement the existing pool of techniques used for forensic fiber examination.

Most textile fibers are organic polymers but contain inorganic constituents (residues from the manufacturing process, additives/finishing agents, or environmental contaminants). Inorganic constituents are only present in minute quantities in single fibers. Therefore, extremely sensitive methods are required for their detection. In this context, XRF techniques have proved to be useful, although they are rarely employed in routine casework. The EPMA method is generally considered relatively insensitive for such an application, whereas XRF and XRFM have been applied, respectively, to carpet fibers, and to colorless acrylic and polyester fibers. The TXRF technique has been investigated for the analysis of colorless samples (single fibers and weighable amounts) of wool, viscose and polyester, and individual automotive carpet fibers. These studies have shown that various fibers made of the same material (i.e. same polymer or same generic class) can be distinguished by their trace element content. Elements of interest are P, Ti, Mn, Sb, Cr, Co, Cu, Zn, Fe, Ca, and Ti. Both XRFM and TXRF appear to be promising methods for the elemental analysis of single fibers. These methods fulfill the requirements of elemental sensitivity and the ability to deal with minute solid samples, including single fibers as small as 5 mm and 2 mm in length, respectively. It should be pointed out that, when dealing with these techniques, it is very important to use appropriate plastic microtools to minimize external contamination. Environmental contamination due to washing or wearing of garments is generally unavoidable. As a result, extra care must be taken when interpreting localized variations and/or when the known sample (e.g. suspect’s garment) has been obtained a significant period of time after the transfer of the unknown sample (e.g. fibers found on the victim).

These techniques can be applied to dyed and colorless fibers, especially in cases where limitations are imposed by similarities in morphological features. It is anticipated that, in the future, with the advances in this field, the elemental analysis of fibers will be more widely used and accepted.

Examples of XRF spectra of carpet fibers are shown in Figures 3 and 4.

4.6 Plastics and General Polymers

Plastics in general, and plastic bags and polymer films in particular, are in common use in a wide range of daily activities. As a result, they are commonly employed in relation to the commission of crime, the most obvious example being packaging material in drug trafficking cases. Other examples include plastic fragments found amongst debris from a bomb scene, pieces of adhesive tapes, traces of plastic bumper bars, etc. The ability to compare and ultimately identify plastics from crime scenes with similar items in the possession of suspects, or
X-RAY FLUORESCENCE IN FORENSIC SCIENCE

For example, elemental profiles of colored polyethylene bags found in illicit drug cases as determined by XRF were found to be very reliable for discriminating between a piece cut from a bag and a batch of bags. Similarly, the value of the elemental profile of green polyethylene garbage bags was investigated using TXRF. The classification model based on the linear discriminant analysis (LDA) of data matrices obtained for Ti, Ca, Pb, Zn, Cu, Cr, and Fe could discriminate samples within a specific package and also different packages. The TXRF method appeared to be more discriminating than differential scanning calorimetry, infrared spectroscopy or optical examination. The technique was found to be particularly useful for the comparison of small amounts of very similar plastics. The usefulness of TXRF for the forensic analysis of polymeric materials, including adhesive tapes, plastic bags and wraps, wire insulation and synthetic fibers, has been recently confirmed.

The EPMA technique was found to be the most discriminating in the sequence FTIR, PGC, and EPMA for the analysis of plastic bumper bars. In this study, 28 bumper bar samples could be classified into 17 categories on the basis of the element profiles. However, the authors pointed out that the nonideal nature of casework samples may reduce the degree of discrimination unless care is taken to present them as polished samples.

Elemental profiles as determined by XRF techniques are obviously very useful and should be incorporated into the forensic protocol for the analysis of plastics and general polymers. However, it should be pointed out that extreme care must be paid to the issue of contamination. In this respect the selection of an appropriate sample preparation protocol is crucial. In addition, the interpretation of the data is not always straightforward.

An example XRF spectrum of a green polyethylene bag is shown in Figure 5.
4.7 Miscellaneous

In addition to the examples described above, a wide variety of materials can be encountered in forensic casework. Many of these materials may require an elemental analysis and therefore can be analyzed using XRF. Several miscellaneous applications are discussed below.

- **Cosmetics** Cosmetic traces, and especially lipstick smears, are sometimes found as evidence on clothing, cigarette butts, crime scene surfaces, etc. They can be successfully analyzed using XRF techniques. The elemental profile may be useful in identifying samples where different pigment formulations are used for similar colors and shades of lipstick made by different manufacturers. Applications of EPMA have been reported by Andrasko\(^{40}\) and by Choudhry.\(^{41}\) Example XRF spectra of cosmetics are shown in Figure 6.

- **Unreacted Explosive Mixtures** Unreacted explosive mixtures, including match head residues, can be found in postexplosion debris or at fire scenes. These residues can be submitted to an elemental analysis including XRF techniques.\(^{42–44}\) The elemental profiles obtained (principally based on Cl, K, S, Si, and other minor elements such as Ca, Ti, Mn, Fe, and Zn) can bring useful information to identify residues and link different cases, or to compare samples found at different locations.

- **Oil and Lubricants** Oil and lubricants can be present as evidence in a variety of forensic cases. The organic characterization of oil and lubricant samples is usually determined by Fourier transform infrared spectroscopy, gas chromatography/mass spectroscopy, fluorescence spectroscopy, and/or high-performance liquid chromatography. Trace element profiling can be carried out and can be useful for discriminating this type of sample. In addition, it appears that engine wear and specific environmental conditions such as soil contamination can contribute to the individualization of a sample.\(^{45}\)

- **Questioned Documents** Materials such as paper, ink, correction fluid, toner, etc. are often analyzed in association with the forensic examination of documents. Common protocols rarely include elemental profile characterization, but it has been shown that elemental analysis, including XRF techniques, can provide still greater discriminating power and reduce the chance of an accidental match.\(^{46–49}\)

5 DISCUSSION AND CONCLUSIONS

A major part of forensic science is based on the chemical characterization of samples of interest. Elemental profile characterization is a common procedure in analytical chemistry, and is therefore often carried out in forensic casework.

Typical forensic samples are generally very small and complex matrices. In addition, due to the legal implications of any forensic procedure, the samples should be kept intact as far as possible. For these reasons,
sensitive solid-state and nondestructive techniques such as XRF are ideal for the forensic scientist. XRF analysis is applicable to a wide range of samples of forensic interest. In addition, specialized XRF techniques such as XRFM and TXRF are extremely interesting from a forensic perspective. These methods fulfil the requirements of good elemental sensitivity and the ability to deal with minute and complex solid samples.

However, it should be pointed out that XRF, as any analytical technique, has some limitations. The major limitation is due to the inhomogeneity of most forensic samples. To discriminate samples of similar make-up, it is often necessary to consider minor elements, because there is little variation in the concentration of major elements present. The intrasample variation can often be close to the intersample variation. It is therefore sometimes difficult to ascertain whether differences are due to the inhomogeneity of the samples or to the fact that the samples come from different sources. In addition, when dealing with highly sensitive techniques such as TXRF, it is very important to pay extra care with sample preparation and handling to minimize external contamination. For example, it is advisable to use plastic microtools rather than metallic implements. It becomes obvious that the comparison and interpretation of elemental profiles requires experience and careful checks to arrive at a meaningful conclusion. Similarly, the data available are often not extensive enough to state that the manufacturing source can be identified on the basis of the elemental profile to the exclusion of all other sources. However, matching profiles are good indicators of a common manufacturing source. When added to the other analytical data available, and in conjunction with industrial inquiries, this information may lead to a positive identification.

The EPMA technique has long been a mainstay in forensic laboratories, particularly for its application to the analysis of GSR. However, with the advent of heavy metal free ammunition, this technique may be of reduced usefulness in the future. More recent developments such as XRFM and TXRF have highly desirable characteristics for the elemental profiling of a wide range of forensic samples. It can be anticipated that these techniques will find increasing use in forensic laboratories in the future.

Industrial Hygiene: Introduction

P.R. Michael  
*Monsanto Company, St. Louis, USA*

C.R. Glowacki  
*CERP, McClellan AFB, USA*

M. Harper  
*University of Alabama at Birmingham, USA*

Industrial hygiene is classically defined as the effort to protect worker health by the recognition, evaluation, and control of stressors in the workplace. Stressors can be in the form of excess energy, for example noise, heat, radiation, or physical stress (ergonomics) or they can be in the form of excessive exposure to a particular chemical element or compound or mixture of compounds. Analytical chemistry plays a fundamental role in identifying and quantifying potentially harmful chemicals in the environment. The determination of chemicals in the workplace is key to all three aspects of industrial hygiene. Recognizing chemicals present in the workplace is sometimes as simple as taking an inventory of the chemicals on hand. Frequently, however, new compounds are formed during chemical reactions and these reactions may not be anticipated in the process design. Evaluating the amounts of chemicals to which workers are actually exposed, for example by the determination of ambient air concentrations, requires the collection of a representative sample typically followed by instrumental analysis to determine the quantities of the compounds or elements in the sample. Once employee exposure has been characterized then possible health consequences can be anticipated and, if needed, appropriate action taken to reduce the exposure. Reliable data are of utmost importance. Not identifying a health hazard can have disastrous consequences ranging from immediate injury or death to more insidious chronic health problems that become manifest years after the exposure has ceased. Conversely, reacting to a hazard that does not exist can result in costly, unneeded engineering modifications or complacency on the part of employees. Follow-up sampling is normally required to judge the efficacy of control measures.

Judgment of “safe” working conditions is usually made by comparing personal exposure concentrations to concentrations believed to be tolerated by the majority of average healthy workers without health consequences. Acceptable exposure concentrations can be established as law by government organizations such as the Occupational Safety and Health Administration in the USA and the Health and Safety Executive in the UK, as voluntary standards such as the Threshold Limit Values set by the American Conference of Governmental Industrial Hygienists, Inc., or in some cases as advisory limits set by the manufacturer of a specific chemical. These concentrations provide a frame of reference for analytical chemists involved with industrial hygiene. However, advances in toxicology and occupational medicine usually result in the identification of biological effects at lower and lower dose levels, challenging chemists to measure smaller and smaller quantities of chemicals in the workplace.

Chemicals can cause local irritation or enter the human body via inhalation, ingestion, or through the skin or mucus membranes. All routes of exposure are relevant to airborne materials and so the measurement of air concentrations is the most common activity in which analytical chemists are involved. Determining materials in the air (which can enter the body through the lungs or which can be deposited in the upper respiratory tract, washed into the gut and ultimately ingested) is a key part of assessing the safety of the workplace. However, in recent years, recognition of significant potential for adsorption through the skin has necessitated the development of techniques to assess surface contamination, the amount of skin adsorption, and permeation through protective clothing.

Once within the body, chemicals can cause acute or chronic systemic effects depending on the chemical species, its dose, and the time interval over which the dose is received, as well as on individual susceptibility. Sampling and analysis of the environment only defines exposure and not actual dose or biological effect. Biological monitoring is a holistic approach for the determination of dose, or, in some cases, the biological effect (e.g. monitoring enzyme efficiency). However, due to a number of complications, it is employed much less frequently than air monitoring. To produce meaningful results biological monitoring must be done in the context of a complete understanding of a compound’s metabolism in the human body, including metabolites, rates of metabolism, and routes of elimination. Biological matrices are much more complex than air samples and analysis methods are usually much more costly to develop and to implement. Also, biological monitoring is confounded by possible off-the-job exposure, interferences related to medications and personal habits, the personal nature and invasiveness of sample collection, coupled with worker concerns about right to privacy. Methods for biological monitoring of organic compounds in the human body are highly dependent on the compound of interest and are not covered in detail here. There are a number of references that provide more background on biological monitoring.
Applications of analytical chemistry in industrial hygiene are closely related to other fields, especially monitoring of the ambient environment, chemical warfare detection, clinical chemistry, and the development and characterization of field portable instruments. In many cases, sample analysis is very similar and it is prudent to keep abreast of advances in those fields. However, the emphasis in industrial hygiene in determining human exposure dictates sampling or sensing with portable, unobtrusive devices and, in the case of biological monitoring, defines the sample matrix as human in origin (typically fluid, tissue, or exhaled breath). In many cases, sample collection, especially when analytes need to be preserved due to instability, becomes an integral part of the analysis method.

Advances in analytical chemistry, such as a greater ability to measure specific compounds at lower and lower concentrations, will benefit industrial hygiene by allowing a better characterization of the work environment. Increasingly, a main interest in industrial hygiene method development is the ability to have rapid, on-site evaluations. Transporting samples back to a laboratory for analysis will undoubtedly continue to play a large role in industrial hygiene, but real time or near real time data allow rapid identification of hazardous conditions and rapid feedback on corrective measures. Improvements in miniature analyzers, remote sensors, and prepackaged chemistries such as enzyme-linked immunosorbent assay techniques will receive a great deal of attention if they can be made sufficiently rugged to tolerate the work environment.

Because chemicals will always play a vital role in industry and since all chemicals are potentially harmful, depending on the dose, the risk of harmful chemical exposure will always exist. In addition, the efficiency of containment measures is not always as good as anticipated and may deteriorate with time. Therefore hazard assessment is required at all stages of industrial hygiene, and exposure monitoring is a vital part of this process.

This section acquaints the reader with applications of analytical chemistry in industrial hygiene. Articles such as Sampling and Recovery Techniques for the Determination of Gases and Vapors in Air and Surface and Dermal Monitoring cover techniques used to obtain samples from the workplace. Laboratory analysis and characterization of those samples is addressed in the articles Chromatographic Techniques in Industrial Hygiene; Spectroscopic Techniques in Industrial Hygiene and Dust, Measurement of Trace Elements in. Devices capable of providing real time or near real time data on site are covered in the articles Direct Reading Instruments for the Determination of Aerosols and Particulates and Sensors in the Measurement of Toxic Gases in the Air. Both laboratory and on-site measurements are discussed in the articles Aerosols and Particulates Analysis: Indoor Air and Carcinogens, Monitoring of Indoor Air. Selected approaches to the analysis of biological monitoring samples are covered by the articles Metals in Blood and Urine: Biological Monitoring for Worker Exposure and Parent and Progeny Compounds in Exhaled Breath, Determination of.

REFERENCES

There is a trend in many analytical techniques towards the use of smaller sizes of the test portion, and sometimes submilligram amounts are being used. The limitation to the size of the test portion can pose the analyst with problems when the amount of material collected is large. Subsampling and preparation of a representative test portion may be difficult if homogenization is impossible or extremely expensive, or if homogenization introduces contamination. An alternative approach has been introduced in the 1990s by the development of large sample neutron activation analysis (LSNAA), later followed by large sample photon activation analysis. These techniques are capable of direct analysis of samples with masses of hundreds of grams to several kilograms. Though the principles and physics of large sample activation analysis are thoroughly understood, the method is still not as versatile or applicable as, for example, normal small sample neutron activation analysis. In this article, the physics of LSNAA is described, including methods of calibration. Examples are given of irradiation and counting facilities and the special aspects of quality control are discussed. Several examples are given of applications of large sample analysis, e.g., for studies related to electronic waste, complete archaeological and cultural artifacts, high-purity materials, and materials of irregular shape.

1 INTRODUCTION

All the routine multielemental analysis techniques (inductively coupled plasma atomic emission spectrometry (ICP-AES), inductively coupled plasma mass spectrometry (ICP-MS), and instrumental neutron activation analysis (INAA), etc.) employ rather small test portions of material, varying from a few milligrams to a few grams of solids or in the range of a few milliliters in the case of liquids (1) (see Table 1). There is even a tendency to go for smaller test portions, such as in solid-state atomic absorption spectrometry (AAS), laser-ablation ICP, and total reflection X-ray fluorescence (XRF) spectrometry. In XRF, the use of quantities larger than required to prepare the target is anyhow meaningless, as the derived information is from the surface layers, representing a few milligrams only.

The limitation to the size of the test portion can pose problems to the analyst when the amount of material collected is large. This is often the case since soils, rocks, plant material, etc. can be more easily and

representatively sampled at quantities in the order of hundreds of grams to kilograms than at quantities less than 1 g. A sample is denoted as “representative” when “it can be expected to exhibit the average properties of the material, environment or population it was taken from”.\(^{(2)}\) Representativeness is a priori preserved when (i) the sampling is performed according to specific, certified norms or when (ii) a truly homogeneous material is sampled. Homogeneity is defined as “the degree to which a property or substance is randomly distributed throughout the material”\(^{(2)}\).

Homogeneity depends on the size of the units under consideration. A mixture of minerals may be inhomogeneous at the molecular or atomic level but homogenous at the particle level. In chemical analysis this unit is obviously correlated with its effect in the conduct of the analysis (e.g. differences in solubility) or in its interpretation. Thus, both from practical and sampling considerations often more material is collected and presented for analysis than can be handled.

Irrespective of the analysis technique selected, attention has to be paid to representative subsampling to obtain a relevant final analytical portion from the originally collected material. When restricting the discussion to the analysis of solid materials, this subsampling may imply sample size reduction techniques and other processing such as sieving, crushing, milling, or blending. Problems of the following types arise:

1. Homogenization is impossible, or extremely expensive, because of material properties. Examples are electronic circuits on printed boards, household waste, and scrap from recycled electronics, automobiles, and plastics. A solution to this problem is to sort the material and to perform individual homogenizations and, subsequently, analyze, thereby increasing the total project costs.
2. The homogenization step results in contamination of the sample. Often the contamination due to crushing or milling is not controllable on every sample type. When processing a large series of samples, careful interim cleaning may get less attention since it is time consuming and therefore expensive.

Testing the degree of homogeneity is a common practice in the preparation of reference materials, but for routine operations, such a procedure, the requirement of analysis and statistical evaluation of at least five or more test portions of each sample, would raise the cost of the analysis considerably.

Considerations from the above indicate that direct analysis of the voluminous solid sample as collected might have advantages, both analytical and economical.

Detection limits in trace-element studies are based on the signal-to-noise ratio. An additional feature of analysis of large test portions is that the detection limit for trace elements may be decreased considerably in case of high-purity materials. This was demonstrated, for example, by Verheijke\(^{(3)}\) in the assessment of impurities in (5 in. diameter) silicon wafers to be used in the electronic industry.

2  LARGE SAMPLE ACTIVATION ANALYSIS

2.1  Large Sample Neutron Activation Analysis

In analytical terms, a “large sample” can be anything exceeding the regular size of a test portion in the process to determine the components of the material. The regular mass of a test portion in neutron activation analysis (NAA) varies from a few milligrams to 1 g. As already indicated, instrumental neutron activation analysis (INAA) has all the potentials to analyze, with adequate accuracy, test portions\(^{(4)}\) in the kilogram range.\(^{(5–8)}\) Both the incoming radiation for activation (neutrons) and the outgoing radiation to be measured (\(\gamma\)-rays) have sufficiently high penetrating power to facilitate NAA of portions of samples weighing kilograms. A “large sample” in NAA is defined as a test portion in which neutron and \(\gamma\)-ray self-attenuation cannot be neglected in view of the required degree of accuracy.
A few phenomena need more attention in large sample neutron activation analysis (LSNAA) than in normal NAA (handling test portions varying from micrograms to a maximum of 0.5 g), where these phenomena usually have only insignificant impact to the degree of accuracy of the results.\(^{(10)}\) In large test portions, e.g., of kilogram size, neutron absorption and scattering result in substantial self-shielding, causing depression of the neutron flux at the center of the sample compared to the periphery. Neutron self-thermalization may cause substantial changes in the neutron spectrum throughout the sample if the sample material also contains, for example, hydrogen.

Similarly, the \(\gamma\)-radiation of the activation products deep inside in the sample will be more strongly absorbed and scattered before leaving the sample than the radiation resulting from, e.g., the surface of the sample; moreover the absorption and scattering increase rapidly at lower \(\gamma\)-ray energies. This effect is denoted as \(\gamma\)-ray self-attenuation. In addition, a sample of, say, 1 kg cannot be considered anymore as a more-or-less “point source” during counting at normal sample–detector distances of, e.g., 10–30 cm, resulting in a corresponding different response of the detector for the \(\gamma\)-radiation. In contrast to conventional INAA with small samples, analysis of test portions larger than a few hundred milligrams requires correction for these neutron self-shielding and \(\gamma\)-ray self-absorption effects, either via calibration or by modeling.

Trace-element determinations in large test portions have been carried out for decades in areas such as well logging, industrial (conveyor) belt analyzers, etc. using isotopic neutron sources such as \(^{252}\)Cf or \(^{241}\)Am(Be). The advantage of isotopic source-based PGNAA compared to normal NAA lies in the fact that the test portion may be analyzed locally rather than having to be taken to the laboratory and on-line information is obtained. Since the output of the sources is rather low, large samples are needed anyhow to obtain a measurable signal, usually from the main components in the material of interest. Industrial analyzers are commercially available for the on-line analysis of cement,\(^{(21)}\) the determination of the sulfur content on coal,\(^{(22)}\) for the detection of explosives in airline cargo,\(^{(23)}\) etc.

Reactor-based large sample PGNAA, i.e., using an external neutron beam, was demonstrated by Sueki et al.\(^{(24)}\) for a pottery sample of 15 cm diameter, 10 cm width, and 0.5 cm wall thicknesses. The neutron beam dimensions were approximately 2 cm \(\times\) 2 cm.

Similar to “normal” LSNAA, also the problems of neutron attenuation and \(\gamma\)-ray self-shielding have to be solved. In the example quoted above, the internal monostandard was used (see Section 5.3). Also, other intact archaeological objects were analyzed by this method, such as bronzes.\(^{(25)}\) Moreover, neutron beams from reactors are relatively limited in dimensions (on the order of 5 cm \(\times\) 3 cm), which sets also a limit to the size of the object activated. This limitation can be overcome by repositioning the sample in the beam.

An advantage of large sample PGNA over normal LSNAA is that no special facilities have to be constructed in the reactor, and that the sample contains hardly any induced radioactivity, which is of importance when dealing with, for example, archaeological or cultural artifacts. The PGNA setup can be standard,\(^{(24)}\) but care has to be taken that the large object does not “transform” into a very intense source of prompt \(\gamma\)-radiation with associated radiation dose hazards for the researchers.
Other methods for standardization have been proposed too, and mostly are based on a priori available information on the (gross) composition of the object; e.g. using Monte Carlo simulations\(^{(26)}\) or neutron transport codes\(^{(27)}\) (“fixed point iteration method”). Degenaar developed a method in which no a priori information is used and the neutron self-shielding is estimated on basis of the attenuation and scattering of the neutron beam, measured outside the sample.\(^{(28)}\)

### 2.3 Large Sample Photon Activation Analysis

Photon activation analysis has the potential to analyze very large samples for reasons similar to NAA: large penetration power of the incident bremsstrahlung photons (typically in the order of several tens of million electronvolts), and similar to NAA, large penetration of the \(\gamma\)-radiation from the induced radioactivity. There is also some similarity to prompt \(\gamma\)-NAA with respect to the size of the object that can be exposed at a time; here also, the sample can be “moved” through the beam to attain a homogeneous activation, or the beam can be scanned over the sample. It introduces an additional complication if the integral sample is counted after exposure: the different activated parts have different decay times but their signals are registered simultaneously. Alternatively, one may choose to limit the sample size.

At the Bundesanstalt fur Materialprufung (BAM) in Berlin, Germany, large sample photon activation analysis has been applied\(^{(26)}\) using the 30 MeV linear accelerator for studies involving samples with sizes in the order of 8 cm height and approximately 2 cm thickness with masses of up to 100–200 g. The measurements were done using a twin detector set up; i.e. the sample was “sandwiched” between two side-looking semiconductor detectors.

One of the advantages of photon activation analysis over NAA is that the corrections for self-attenuation of the incoming bremsstrahlung photons are relatively easy to be applied on the basis of fluence rate monitors positioned before and after the sample.\(^{(29)}\) Moreover, given the high energy of the photons, this attenuation is mostly relevant for thick targets with high average atomic number.

Large sample photon activation analysis has many interesting aspects and advantages compared to LSNAAs, including its capability to detect elements such as C, N, and O, as well as Tl, Bi, and Pb. However, the number of photon activation analysis laboratories worldwide is very small and most of the large sample activation analysis studies are done with neutrons. For these reasons, this type of large sample analysis is not further elaborated upon in this article, and the reader is directed to the available literature.\(^{(29)}\)

### 3 Measurement Equation of Large Sample Neutron Activation Analysis

The basic measurement equations of NAA by which the mass of the unknown element is calculated directly demonstrates the fact that the technique does not set a priori constraints to the mass of the sample analyzed:

\[
m_{\text{unk}} = m_{\text{std}} \frac{(A_{\text{unk}})}{(A_{\text{std}})} R_{\phi} R_{\gamma} R_{\eta} R_{\gamma} R_{\sigma} R_{\gamma} R_{\text{inh}}
\]

(1)

\[
A_0 = \Phi_{\text{th}} \sigma_{\text{eff}} N_{\text{Av}} \theta m M (1 - e^{-\lambda t_d}) e^{-\lambda t_d} (1 - e^{-\lambda t_{\text{inh}}}) \frac{\gamma \epsilon}{\lambda}
\]

(2)

in which the subscripts “unk” and “std” refer to unknown and standard, respectively, and:

- \(A_0\) = the area of the relevant peak in the \(\gamma\)-ray spectrum, corrected for differences in decay and measurement time between the unknown (\(x\)) and the standard (\(s\));
- \(R_\phi\) = ratio of isotopic abundance of the element of interest in test portion and standard (often \(= 1\));
- \(R_\gamma\) = ratio of thermal neutron fluence rates in test portion and standard;
- \(R_{\text{En}}\) = ratio of neutron energy distribution in test portion and standard;
- \(R_\sigma\) = ratio of effective activation cross sections for the test portion and standard at the different neutron energy spectra;
- \(R_{\text{ns}}\) = ratio of the neutron self-shielding in test portion and standard;
- \(R_{\text{inh}}\) = ratio of the \(\gamma\)-ray self-attenuation in test portion and standard; and
- \(R_{\gamma\text{ss}}\) = ratio of the \(\gamma\)-ray self-attenuation in test portion and standard.

Also,

- \(\Phi_{\text{th}}\) = the thermal neutron fluence rate (cm\(^{-2}\)s\(^{-1}\)),
- \(\sigma_{\text{eff}}\) = the effective absorption cross section (cm\(^2\)),
- \(N_{\text{Av}}\) = the Avogadro’s number (mol\(^{-1}\)),
- \(\theta\) = the isotopic abundance,
- \(m\) = the mass of the irradiated element (g),
- \(M\) = the atomic mass number (g mol\(^{-1}\)),
- \(\lambda\) = the decay constant of the radioisotope formed (s\(^{-1}\)),
- \(t_d\) = the irradiation duration (s),
- \(t_{\text{inh}}\) = the decay time (s),
- \(t_{\text{inh}}\) = the (live time) measuring time (s),
- \(\gamma\) = the abundance in the nuclear decay of the \(\gamma\)-ray measured, and
- \(\epsilon\) = the full energy photopeak efficiency of the detector for the energy of the \(\gamma\)-ray measured.
Many of the correction terms, \( R_i \), can often be neglected in normal sample analysis but some of them like \( R_{\text{net}}, R_{\text{yxt}}, R_{\text{E}}, R_{\text{E}} \), and \( R_{\text{inh}} \) become significant in large sample analysis. As such, algorithms in large sample NAA differ from normal NAA by the calculation/estimation of

- the neutron self-shielding and/or neutron fluence rate profile inside the test portion,
- the \( \gamma \)-ray self-attenuation,
- the volumetric photopeak source efficiency of the detector, and
- the impact of extreme inhomogeneity effects.

There are many approaches for these calculations, varying from pure theoretical modeling, Monte Carlo modeling, and modeling using a priori available information about the test portion composition to pragmatic empirical estimations of the correction factors. Modeling may even be avoided when, e.g., for routine applications a representative well-characterized (large sample) standard – even a reference material – is available. These standardization methods are further discussed below.

### 4 INSTRUMENTATION

#### 4.1 Neutron Sources for Large Sample Activation Analysis

The type and strength of the neutron source and energy characteristics play an important role in any type of NAA including LSNA, as the radioactivity produced is directly proportional to the neutron flux \( \phi \) and energy-dependent neutron absorption cross section \( \sigma \). The neutron source should provide a sufficiently high neutron fluence rate so as to keep the product of neutron fluence rate and large test portion mass almost equal to that in small test portion NAA. This criterion indicates that for test portions with masses in the order of 2 kg a neutron fluence rate of approximately \( 5 \times 10^{12} \times 0.2/2000 = 5 \times 10^8 \text{ cm}^{-2} \text{ s}^{-1} \) would result in an adequate induced radioactivity during the irradiation time, similar to that applied in conventional NAA in which a 200 mg test portion is processed. Fluence rates on the order of \( 10^9 \text{–} 10^{10} \text{ cm}^{-2} \text{ s}^{-1} \) are found at an extended distance from the core of small and medium-sized reactors in beam tubes, and in thermal columns (TCs). However, low fluence rates can also be realized – or even may be preferred – by lowering the reactor power because of fuel economy considerations. Table 2 also provides an indication of typical neutron sources available to provide the required neutron fluence rate.

The advantage of reactor TCs above, e.g., poolside facilities, is that the longitudinal neutron flux gradient (i.e. horizontally away from the reactor core) over the sample is much less steep because of the multiple neutron scattering in the graphite inside the TC, as can also be derived from the differences in thermal neutron diffusion length in carbon and water, viz., 64.2 and 2.76 cm, respectively. Rotating the sample along its vertical axis compensates partly for these gradients. However, in some materials the neutron self-attenuation combined with the neutron flux gradient may result in situations in which the center of the test portion is hardly activated compared to the periphery. In such cases, the measured \( \gamma \)-rays originate mainly from the periphery and the analysis result will apply merely to the outermost layers of the sample rather than reflecting the bulk composition. In such facilities, the approach is to set limits to the dimensions of the test portion. Moreover, neutron self-moderation will occur owing to the less thermalized neutron spectrum in poolside facilities, resulting in difficulties in the calculation of the element amounts.

Neutron fluence rates \(<10^{10} \text{ cm}^{-2} \text{ s}^{-1} \) may also be attainable with isotopic neutron sources and high-intensity neutron generators, and in (reactor-based) external neutron beams. \(^{252}\)Cf is probably the most attractive isotopic neutron source from the point of view of the neutron spectrum shape and easy thermalization aspects. However, the short half-life (2.64 years) may be seen as an economical disadvantage. Other isotopic neutron sources have a relatively hard neutron spectrum, resulting in relatively low thermal neutron fluence rate equivalents. The applicability of such neutron sources may, therefore, be limited to the determination of the major components in a sample.

Neutron generators (3–14 MeV) have their own scope of applications. One of the problems in using neutron generators and isotopic neutron sources is that the neutron fluence is anisotropic and therefore the neutron flux seen by a large sample is not the same in all parts of the sample. This can be overcome to some extent by rotating the test portion during irradiation. Given the fact that the thermal neutron fluence rate in, e.g., a D-D
(deuterium ions on a deuterium target) generator is of the order of $10^4$ lower than in research reactors, an increase in sample mass of at least $10^5$ (i.e. from 200mg to 2kg) would be needed to compensate for this low thermal fluence rate.

An advantage of large (kilogram size) sample NAA with D-D generators over reactors is that the sample may be quickly removed from its irradiation position upon shutting down the accelerator, facilitating the measurement of radionuclides with short half-lives. For samples in the order of tens of grams, pneumatic facilities may be designed. Larger sample masses may also be considered for delayed neutron counting procedures to reach lower minimum detectable amounts, although this implies that a larger delayed neutron counter is needed too.

However, several technological obstacles exist both with isotopic neutron sources as with neutron generators, such as the large void needed within the moderator of the device. Moreover, since these moderators are often based on hydrogenous materials such as polyethylene or paraffin, steep flux gradients may occur over the sample, similar to those outlined earlier for poolside reactor facilities. The large sample approach may also be considered for irradiation with the sub-fast neutrons, although here an increase in sample mass from, e.g., 200mg to 200g might be sufficient for reaching the sensitivity required. However, an additional problem is that large sample masses will increase the effect of neutron self-moderation.

Most of the external neutron beams from nuclear reactor, with neutron fluence rates of $10^5 - 10^6$ cm$^{-2}$ s$^{-1}$, are suitable for PGNAA. An advantage associated with PGNAA is the flexibility in choosing the mass and shape of the test portion. However, one should be careful in increasing the test portion mass, as it might adversely affect the measurements because the background is sample dependent in PGNAA. It becomes severe particularly in the cases where the hydrogen or boron fraction in the large test portion is high, as it results in an extremely intense source of prompt $\gamma$-radiation, which will affect the results. External neutron beams of isotopic neutron sources have usually neutron fluence rates of $<10^7$ cm$^{-2}$ s$^{-1}$ and can in principle be used for PGNAA, though the energy definition becomes a tedious problem. Steep neutron gradients over the sample occur in neutron beam activation analysis too.

4.2 Irradiation Facility

Transferring the test portions to the irradiation position of the neutron source is usually done with pneumatic/hydraulic transfer facilities and/or manually or automatic loading facilities. Most of the pneumatic facilities are designed to handle volumes up to 5–50 mL, which are placed in a sample carrier known as “rabbit”. Use of rabbit systems places constraints on the sample shape so as to maintain the defined geometry. In principle, it is possible to transfer test portions up to 1kg or more through such facilities – such big systems already exist for transferring documents in offices and banks; however, it is yet to be explored and examined whether large rabbits can be obtained with the required specifications (quality of the rabbit materials, purity, and radiation/mechanical resistance) for application in reactors.

In some reactors TCs are available for accommodating a large sample irradiation facility (see Figures 1 and 2). Samples are placed in the irradiation position of the TC by the mechanical movement of a tray that houses the sample in a defined position. In Table 3, suggestions for facilities for irradiation of test portions of different masses are indicated.

There are various design aspects to be taken into account for irradiation facilities:

1. A large-volume facility near the core of a nuclear reactor creates a void in the reactor’s reflector, whereas loading and unloading may cause unwanted fluctuations in the core’s reactivity. Moreover, a high amount of $^{41}$Ar will be produced from activation of the air in the container.

2. The thermal neutron fluence rate gradient in the water reflector of a light-water-moderated reactor is quite steep, typically by a factor of 3 per each 3 cm, which is due to the neutron diffusion length (2.84 cm) in water. Such a strong gradient would also create an unwanted strong flux variation over the large test portion to be activated. This may be corrected for by rotating the sample during counting, by mixing the sample after irradiation, or by the use of in situ relative efficiency method. Mixing, however, eliminates information about inhomogeneities. The problem of heterogeneity may also be addressed by dividing the large test portion into many smaller fractions, to be processed individually followed later on by combining of the results.

3. Large hydrogen mass fractions may result in neutron spectrum changes over the test portion volume due to self-thermalization. This phenomenon is difficult to correct for mathematically, and may be an additional reason to consider an irradiation facility with well-thermalized neutron spectrum, for instance, to be realized in a TC.

4. Large sample activation facilities at isotopic neutron sources must be designed in such a way that adequate shielding is ensured against the prompt $\gamma$-rays, which will be several orders of magnitude higher than with normal small samples.
A few of the large sample NAA reactor facilities that are currently operational are given in Table 4.\textsuperscript{35} Large sample PGNAA facilities have been realized in Hungary and Japan. Isotope neutron source-based large sample PGNAA facilities are in use in some places.\textsuperscript{36}

### 4.3 Sample Containers for Irradiation

The large sample container itself may be of any shape and type. A wide-neck bottle is easy to fill when coarse material has to be analyzed (Figure 3).\textsuperscript{5} A container of inexpensive plastic may be preferred, as the impurities in the plastic itself (blank contribution) may be neglected at a given sample size (see Table 5). If the contribution from the sample holder is substantial, the irradiated large samples may also be easily transferred after irradiation into nonirradiated containers and possible small losses during transfer can be neglected in view of the large mass of the test portion. As such, a Marinelli beaker geometry or multisample container (Figure 4)\textsuperscript{37} may...
4.4 Counting Facility

Very large Ge detectors are available (crystal sizes up to 400–800 cm³, comparable to “relative efficiencies” of 100–200%). Such big detectors are an additional tool to maintain adequate sensitivity in NAA. Side-looking detectors (“horizontal dipstick”) have the advantage that cylindrical samples, positioned perpendicular to the detector axis, can easily be rotated around the sample axis to reduce geometrical effects. Vertical dipstick detectors have the advantage to measure large samples in the Marinelli beaker geometry. Well-type Ge detectors can handle test portion volumes of up to approximately 8 mL, and thus have their own niche in large sample NAA, especially as an addition to enhance sensitivity for test portions in the grams range.

In general, it is preferable to count the large sample by placing it at a certain distance from the detector end cap to minimize complications in the efficiency calculations, in particular in the coincidence summing corrections. The distance between the test portion and detector is guided by the sample activity; the higher the activity, the farther the sample to be placed from the detector. Automatic sample changing can be realized irrespective of the sample size. Sample changers are already commercially available for containers with volumes up to 1 L, although they have been designed for the Marinelli beaker measurement.

Figure 3  Large sample container (diameter 12 cm, height 20 cm) in front of side-looking Ge detector (cryostat diameter 9 cm).

Figure 4  A multisample container.\(^{(37)}\)

Adequate shielding of the stored samples remains, of course, a prerequisite.

Different detector calibration approaches are needed – taking into account voluminous photo peak efficiency, \(\gamma\)-ray self-attenuation, and coincidence summing correction if Marinelli beaker geometries or multisample containers are applied. In the multisample container setup, as the geometry for each container is the same, one can start with one container and measure up to 20 samples according to their decay.

The spectrometer may have to be equipped with a separate device to allow the determination of the effective \(\gamma\)-ray linear attenuation coefficients using a multi-\(\gamma\)-ray pencil beam of an external source (e.g. \(^{152}\)Eu). An example of such a setup is given in Figure 5.

It may be necessary to collimate the detector in case the localization of the inhomogeneity is the subject of interest in large sample analysis (see Figure 6). Such a setup will allow, in principle, for emission tomography of the activated sample.\(^{(38)}\)

More advanced spectrometer systems may be designed, in which two or more Ge detectors surround the large sample to create nearly \(4\pi\) geometry of the detectors.\(^{(29)}\)

The individual spectra can be added later to create a composite spectrum with better statistics.

The \(\gamma\)-ray spectrometer should be equipped with dedicated high-count-rate electronics if the induced radioactivity to be measured would result in a count rate \(>20\,000\,s^{-1}\). The prerequisites are a transit–reset preamplifier and pulse processing electronics (analog or digital), allowing for on-line dead-time compensation, e.g., based on the loss-free counting principle.\(^{(39)}\) The latter is relevant only if count rates vary significantly during the counting time, as may be the case in counting radionuclides with very short half-lives (in the range of seconds to several minutes).

It is interesting to take note that there are a few applications where counting could be carried out using well-type scintillation detectors. In the cases where major components only have to be analyzed and the neutron sources are isotope based, then the resulting activity could be low and the \(\gamma\)-ray spectra might be relatively simple, which could be measured using high-efficiency scintillation detectors. Large sample NAA with isotopic sources and the use of scintillation detectors may be considered as an additional opportunity to further enhance the sensitivity. One may even construct a simple \(4\pi\) detector by putting two well-type detectors against each other.

5 CALIBRATION

Determination of the elemental masses in large sample NAA may be done as in small sample NAA, via

- the absolute method,
- the comparator method, or
- the internal standard method.

5.1 Absolute Method

The absolute method for standardization in NAA is based on using known values for neutron fluence rate and activation cross sections, derived either from previously performed measurements or from reactor physics estimations (neutron fluence rate) and from the literature data (cross sections); the same is the case with $\theta$, $N_{AV}$, $M$, $\sigma_{\text{eff}}$, $\gamma$, and $\lambda$. For many $(n,\gamma)$ reactions and radionuclides, the parameters $\sigma_{\text{eff}}$, $\gamma$, and $\lambda$ are not precisely known, while in some cases $\theta$ also is not known accurately. Since the various parameters are often achieved via independent methods, their individual imprecisions will add up in the calculation of the elemental amounts, leading to large systematic errors. This method is best applicable if the composition of the sample matrix is well established in advance, as is the case, e.g., when dealing with pure materials. It is well known that even in normal NAA this approach may not yield highly accurate data but still the results may be adequate
for the intended purpose. Still, additional estimates are needed for correcting the neutron fluence rate gradient and the $\gamma$-ray self-absorption. The first may be done using simplified models or using neutron transport codes, and the second after simple transmission measurements or using tabulated linear attenuation coefficients in case the sample is well defined with respect to its composition.

5.2 The Comparator Method

The test portion is irradiated together with a calibration sample containing a known amount of the element(s) of interest. The calibration sample is measured under (preferably) the same conditions as the sample (sample-to-detector distance, sample size, and if possible composition). From a comparison of the net peak areas in the two measured spectra, the mass(es) of the element(s) of interest can be calculated (see above, Equations (1) and (2)):

$$mass_{unk} = mass_{std} \frac{(A_{0,\gamma})}{(A_{\gamma})} R_0 R_\phi R_{En} R_{\sigma} R_{mass} R_\gamma R_{\gamma \gamma} R_{inh}$$

The relative standardization based on element standards is not immediately suitable for laboratories aiming at the full multielement powers of INAA. It is virtually impossible to produce a multielement standard containing known amounts of all 70 detectable elements with sufficient accuracy in a volume closely matching the size and the shape of the samples. For this reason, some laboratories prefer to use (certified) reference materials as a multielement standard. However, if dealing with large samples (gram to kilogram size), the use of (certified) reference materials is not practical (major differences may exist in neutron spectrum characteristics in the real sample and in the standard), economical (reference materials are expensive and large sample analysis would imply a high consumption rate), or ethical (certified reference materials are produced for method validation purposes, not necessarily for calibration).

Multielement INAA based on the relative standardization method is feasible when performed according to the principles of the single comparator method. Assuming that all relevant experimental conditions are stable over time, standards for all elements are co-irradiated, each in turn with the chosen single comparator element. Once the sensitivity for all elements relative to the comparator element has been determined (expressed as the so-called $k$-factor, see Section 5.3), only the comparator element has to be used in routine measurements instead of individual standards for each element.

5.3 Single Comparator Method

Originally, the single comparator method for multielement INAA was based on the ratio of proportionality factors of the element of interest and of the comparator element after correcting for saturation, decay, counting, and sample weights. Girardi et al.\(^{(40)}\) defined the $k$-factor as

$$k = \frac{M_1 Y_{c, k, \gamma} \sigma_{eff, c}}{M_c Y_{c, \gamma} \sigma_{eff, t}}$$

in which the subscripts “t” and “c” refer to the element of interest in the sample and comparator, respectively. Mass fractions can then be calculated from these $k$-factors; for an element determined via a directly produced radionuclide, the mass fraction $\rho$ follows from

$$\rho = \frac{(A/SDCw)_t}{(A/SDCw)_c} \cdot k$$

where $S = (1 - e^{-\lambda \cdot t})$

These experimentally determined $k$-factors are often more accurate than those calculated on basis of literature data as in the absolute standardization method. However, the $k$-factors are valid only for a specific detector, a specific counting geometry, and the irradiation facility and remain valid only as long as the neutron flux parameters of the irradiation facility remain stable.

The main problem of the single comparator method in LSNAA is that differences in neutron exposure, $\gamma$-ray attenuation, and volumetric counting efficiency between comparators and samples all have to be accounted for. In normal NAA, most of these differences can be neglected, also because the comparators are co-irradiated with the samples. But in LSNAA this may be practically impossible; the irradiation facility may not be spacious enough, and substantial difference may exist in the neutron exposure and flux gradients. Only if the neutron flux spectrum is well known – as in TCs – and the neutron fluence rate gradient can be established in each individual test portion, the comparator method provides an opportunity for applicability. In that case, even the $k_0$-based method for standardization may be applied.

The comparator method is, however, very well usable for large sample analysis of, e.g., large liquid samples such as water or oil since standard samples with element spikes into a similar matrix can easily be prepared.

5.4 $k_0$-Based Method for Standardization

At the Institute for Nuclear Sciences in Ghent, Belgium, an attempt has been made to define $k$-factors that should be independent of neutron flux parameters as well as spectrometer characteristics.
The expression for the activation reaction rate can be written as
\[ R = \Phi_{th} \sigma_0 + \Phi_{epi} I_0(\alpha) \]  
(6)

The ratio \( f \) of the thermal neutron flux and the epithermal neutron flux is \( f = \Phi_{th}/\Phi_{epi} \) and the ratio of the resonance integral and the thermal activation cross section can be expressed as \( Q_0(\alpha) = I_0(\alpha)/\sigma_0 \), thus the effective cross section is
\[ \sigma_{eff} = \sigma_0 \left( 1 + \frac{Q_0(\alpha)}{f} \right) \]  
(7)

The \( k_0 \)-factor is now defined as
\[ k_0 = \frac{1 + (Q_{0,0}(\alpha)/f) \epsilon_c}{1 + (Q_{0,0}(\alpha)/f) \epsilon_t} = \frac{M \epsilon_0 \sigma_{0,1} \gamma_c}{M \epsilon_0 \sigma_{0,1} \gamma_t} \]  
(8)

and the mass fraction, again for an element determined via a directly produced radionuclide, is found from
\[ \rho = \frac{1 + (Q_{0,0}(\alpha)/f) \epsilon_c}{1 + (Q_{0,0}(\alpha)/f) \epsilon_t} \frac{(A/\text{SDCw})_c}{(A/\text{SDCw})_t} k_0 \]  
(9)

The \( k_0 \)-factor has thus become a purely nuclear parameter for the thermal neutron spectrum. In the \( k_0 \) convention, Au is proposed as the comparator element. The neutron flux parameters \( f \) and \( \alpha \) no longer cancel out in concentration calculations and must be measured in each irradiation facility, preferably even for each irradiation and sample.\(^{[41]}\) The \( k_0 \)-factors are used in Delft for the analysis of very large samples.

### 5.5 Internal Monostandard Method

In the internal monostandard method, one of the radionuclides produced during activation of the test portion is used as monostandard. The rationale behind this is that the effect of neutron spectrum perturbation is the same for this parent element of this radionuclide as well as for all other elements in the sample; as such there is an implicit assumption that the test portion is “macroscopically” homogeneous.

In the case of internal monostandard method using TC irradiations followed by \( \gamma \)-spectrometric method, the ratio of mass \( m \) of an element \( x \) in the test portion \( t \) to mass of the internal comparator element \( c \) in the sample is given by Equation (10):
\[ \frac{m_t}{m_c} = \frac{(\text{S.D.C}) \cdot (f + Q_s(\alpha))_x}{(\text{S.D.C}) \cdot (f + Q_s(\alpha))_t} \cdot \frac{A_{Ax}}{A_{Ac}} \cdot \frac{(\epsilon_\gamma)_t}{(\epsilon_\gamma)_c} \cdot \frac{1}{k_{0,c}(x)} \]  
(10)

Here, \( k_{0,c}(x) \) represents the relative sensitivity of element \( x \) with respect to \( y \) and is calculated from the \( k_{0,\text{Au}} \) factors in the literature.

The internal monostandard method either results in elemental mass ratios (element of interest vs. monostandard element) and thus may serve for comparative studies, or, in the case of, e.g., materials of high purity and known stoichiometry, directly into mass fractions of the elements of interest if (one of) the major component(s) is used as the monostandard element.

#### 5.6 Neutron Fluence Rate Monitoring

Neutron fluence rate monitoring is needed for the \( k_0 \) method of standardization and may be done noninvasively with the flux monitors outside the sample, as well as by inserting flux monitors inside the sample. The first approach may use, e.g., the neutron depression outside the large sample to estimate the neutron flux distribution;\(^{[42]}\) the second approach provides direct information on the flux distribution.\(^{[43,44]}\) The first approach is applied in Delft for large sample irradiations in the reactor’s TC.\(^{[5]}\) During the irradiation, the sample is surrounded by four flux monitors at any desired height around the sample. Since the unperturbed neutron flux gradient in the TC can be derived from the irradiation of a pure graphite sample, the neutron flux depression outside the sample can be estimated (Figure 7). This forms the basis for estimating the effective neutron diffusion length and neutron diffusion coefficient. Finally, the overall correction factor is calculated – which reflects how the large sample compares to a small sample – using the volume efficiency of the Ge...
detector, the neutron diffusion length and coefficient, and the effective linear attenuation coefficients.

Changes in the neutron spectrum due to self-thermalization are much more difficult to deal with, as these are not easy to monitor. The extent of this effect depends, of course, on the neutron spectrum shape and the fraction of epithermal and fast neutrons compared to the thermal neutrons. In TC facilities, the ratio of thermal over nonthermal neutrons may be much larger than a factor of 1000, eliminating the significance of neutron self-thermalization. The user of the irradiation facility should be familiar with this phenomenon, and a priori information must always be collected about the sample composition so as to estimate the extent of these effects and to decide if empirical correction factors can be applied or if additional in situ monitoring is needed (i.e. invasive, by inserting suitable monitors inside the sample).

5.7 γ-Ray Self-Attenuation

The γ-ray self attenuation correction is relatively easy to establish once the effective linear attenuation coefficients are available, either by measurement or by calculation from the approximate (or well-known) elemental composition. A multi-γ-ray emitting source, with γ-ray energies distributed over the entire range of interest (such as 152Eu, 182Ta) can be used for this. A nearly pencil beam geometry can be created by locating this source behind a pinhole collimator, and the γ-ray transmission can be measured at several heights along the sample. This forms the basis for the estimation of the effective linear γ-ray attenuation coefficients.

The volumetric photopeak efficiency can be determined by Monte Carlo modeling, but this requires precise information about the inner geometry of the cryostat and detector configuration (including the dead-layer thickness). Empirical curves may be determined using standard sources in water, as the self-attenuation can simply be subtracted from the measured efficiency. In situ relative detection efficiency in a voluminous sample was determined using the multi-γ-emitters produced in the sample, and was adequate to calculate mass ratios with respect to the comparator using Equation (5).\(^{(45)}\)

Pragmatic approaches have been suggested in which the large sample, after activation, is repacked into many small-diameter containers that are placed in a cylindrical holder surrounding the detector. If the detector crystal is perfectly symmetrically mounted inside the cryostat, the detection efficiency for each of the positions around the detector is the same, which simplifies the calculations. Besides, the dimensions of the small containers can be chosen such that γ-ray attenuation effects may be neglected.

It should be noted that the γ-ray spectrum due to the natural radioactivity of the sample material has also to be measured in large sample analysis, prior to the activation. These “sample background” peaks in the γ-ray spectrum should be separately treated later on in the neutron and γ-ray self-attenuation corrections.

5.8 Extreme Inhomogeneities

Combination of correction algorithms for neutron and γ-ray self-attenuation as well as for the volumetric photopeak efficiency yields an “overall correction factor”, which reflects the difference between the actual detector response for a given γ-ray energy and the theoretical detector response if the sample were a massless point source located in the large sample’s center, without any neutron and γ-ray attenuation.\(^{(9)}\)

In these corrections, it is assumed implicitly that both trace elements and major (matrix) elements in the sample are homogeneously distributed on a macroscopic scale. If this condition is not met, there is a high probability that owing to the neglect of inhomogeneities the concentrations determined are not correct. How large these deviations may be as a result of such neglect has been studied via computer simulations. Inhomogeneities may influence the results of the irradiation as well as of the measurement; therefore, both have been treated separately. Inhomogeneous matrix composition has been modeled by composing a sample of cylinders with strongly differing neutron or γ-ray attenuation properties. Inhomogeneity for trace elements has been simulated by modeling extreme distributions of a trace element with either neutron or γ-ray attenuation properties, strongly differing from those of the main composition of the sample.\(^{(40,46)}\) Both inhomogeneities in matrix composition (e.g., layered structures) and trace-element inhomogeneities (e.g., “hot spots”) were taken into account.

Obviously, the results of these simulations demonstrated that false concentrations may be obtained if inhomogeneities are not accounted for in the interpretation step of large sample INAA. The smallest errors may occur for matrix inhomogeneities; the most pronounced effects can be expected when the trace element of interest is distributed either on the outside or on the axis of the cylindrical sample.

In these simulations, materials or elements were selected with neutron and γ-ray attenuation properties that were strongly different from the rest of the sample; as such they may be considered as “extremities”, and the consequences on the inaccuracy of the results rather indicate “worst case” conditions.
5.8.1 Determination of Inhomogeneities

The presence of extreme inhomogeneities in large samples may be considered a nuisance. On the other hand, large sample analysis is a unique tool for determining these inhomogeneities without destroying the test portion. To this end, sample scanning using a collimated detector has been introduced, and it is assumed that the sample consists of volume elements that individually are considered homogeneous.

The set of spectra constituting one scan is statistically evaluated to determine whether fluctuations over the scan of the count rates of $\gamma$-rays of a given energy are only due to Poisson counting statistics or are also due to inhomogeneities in the sample. If inhomogeneities have only a layered structure in the direction of the cylinder axis of the sample, the sample can be analyzed layer by layer, and for the most extreme cases the analysis can be performed for each voxel separately. An example of a collimated detector system for large sample scanning is shown in Figure 6.

Baas et al.\textsuperscript{(38,47)} developed a method for the detection of local inhomogeneities. The count rate in each channel of each segmented measurement can therefore be compared with the average count rate in each channel after summing all individual measurements. Such a comparison, taking into account uncertainties, is made analogous to the $\zeta$-score principle. Values of $|\zeta| > 2$ or $> 3$ (depending on the analyst’s fitness-for-purpose criterion) indicate a local inhomogeneity at the respective $\gamma$-ray energy in a particular voxel. This approach is visualized in Figure 8. A bottle of approximately 25 cm length and 8 cm diameter filled with soil was irradiated in the large sample facility in Delft. The induced radioactivity was measured with a 96% Ge detector, collimated with a 10-cm-thick Pb collimator with a 2-cm split opening. The figure shows the $\zeta'$ scores for each channel number ($\gamma$-ray energy) along the height of the sample. From the zoomed details it can clearly be seen that strongly deviating $\zeta$-scores occur at, e.g., 439 and 1115 keV, indicating an inhomogeneity for zinc. In addition, the histogram of all $\zeta$-scores in this figure provides also an insight into the presence of this inhomogeneity.\textsuperscript{(47)}

6 QUALITY CONTROL

The high degree of accuracy in normal activation analysis results from decades of experience in the development of certified reference materials. Many sources of error and the quantification of their impact are known.\textsuperscript{(48,49)} Methods commonly referred to as quality control practices have been developed to inspect the occurrence of errors during the analysis, whereas implementation of quality assurance contributes to minimizing and even avoiding the occurrence of errors. The known sources of error in normal activation analysis may occur in large sample analysis too. Some of them – such as $\gamma$-ray self-attenuation and neutron/photon fluence rate, or neutron spectrum gradients – have much larger effects. Extreme inhomogeneities are an additional phenomenon in large sample analysis,\textsuperscript{(46)} with an impact on the degree of accuracy.

Quality control in normal activation analysis includes the simultaneous analysis of well-characterized quality

---

Figure 8 Energy- and position-correlated $\zeta$-scores (see text) of measured radioactivity, indicating location of inhomogeneities in a sample of 20 cm height and 10 cm diameter.
control samples, blanks, and sometimes duplicates. In addition, inspection of the intensity ratios of γ-ray peaks of a given nuclide and/or the quantified results based on different radionuclides formed from a given element also provide a unique opportunity to inspect for errors. The applicability of these quality control approaches for samples of increasing mass is given in Table 6.

It is clear that basic problems emerge when extending the traditional approaches to samples with weights of more than a few grams. Firstly, well-characterized control samples of the size of large samples (several grams to kilograms) are either very expensive to use or not available at all. Secondly, large sample analysis may be required because of the heterogeneity of the object, which cannot be simulated by a control sample even if it were available. Thirdly, duplicates – assuming identical composition in mass fraction and in degree of homogeneity – may probably not be available when larger sample masses are needed. The problem related to the blank – impurities in the sample container and/or contamination – has, on the contrary, a smaller impact on the final result since the increase in the ratio of sample mass to container mass may result in negligible contribution of the blank (Table 5).

New strategies have to be developed to control the analytical quality in large sample analysis. One of the opportunities is to continue with the use of performance indicators, derived from the actual sample analyzed. In fact, this is not different from most quality control procedures in, e.g., manufacturing and production, in which the quality of a final product depends on predefined specifications being met, such as dimensions, tolerances, mass, color, or operation characteristics. The inspection of γ-ray intensity ratios and the use of different radionuclides of one element are already examples of such a form of quality control in activation analysis. This approach can further be extended to other sample/material characteristics on the basis of physical sample properties such as γ-ray self-attenuation and neutron attenuation parameters, as well as via the degree of inhomogeneity (Table 3).

### 6.1 Quality Control in Large Sample Analysis

Some materials may be difficult to be processed to such homogeneity that representative subsamples can be taken at the <1 g level. For such materials, it may be advantageous to analyze much larger quantities without homogenization and to assume that the inhomogeneities are randomly distributed throughout the sample, so that the entire quantity can be considered as homogeneous. However, this assumption has some limitations. Overwater and Bode demonstrated the impact of extreme inhomogeneities on the correction mechanisms for the attenuation of γ-ray attenuation and neutron self-shielding.\(^{46}\) Inhomogeneities with strong γ-ray absorbing properties have stronger effects on the degree of accuracy than those with strong neutron absorbing properties. It is therefore relevant to inspect for the presence of such extreme inhomogeneities in order to decide on the value of the finally calculated mass fractions. Two opportunities to inspect such inhomogeneities are given here.

The effective linear γ-ray attenuation coefficient is usually determined by measuring the transmission of γ-rays of different energies emitted by an external source with known emission rates.\(^{9,45}\) The values of the effective linear attenuation coefficients may be estimated using the tabulated values for the elements. Typically, for example, biological and geological material values of ∼0.15 cm\(^{-1}\) < μ < ∼0.60 cm\(^{-1}\) at ∼100 keV; ∼0.12 cm\(^{-1}\) < μ < ∼0.25 cm\(^{-1}\) at ∼300 keV; and ∼0.05 cm\(^{-1}\) < μ < ∼0.15 cm\(^{-1}\) at ∼1000 keV can be found. A “bandwidth” of the linear attenuation coefficient can thus be determined at different γ-ray energies for different types of materials (e.g. environmental, geological) (Figure 9). This can assist in inspecting whether the experimentally determined attenuation coefficients have realistic values. Moreover, if scanned measurements are carried out, an indication of local (layer-type) inhomogeneities with strong γ-ray absorbing properties may already be obtained. An example of this approach is given in Figure 10. The transmission of the γ-rays of a \(^{152}\) Eu source was measured at different heights along a ∼1–m long, ∼15–cm diameter soil drill core sample prior to neutron activation. The effective linear attenuation coefficients for each of the γ-ray energies were fitted with a polynomial so as to estimate the effective linear γ-ray attenuation at other γ-ray energies. The attenuation coefficients at 100, 300, and 1000 keV all fall within the expected bandwidths. There are no indications in this example for layer inhomogeneities with strongly differing γ-ray absorbing properties.

Y = yes, application possible; N = no, not possible; l.r. = less relevant (see text); n.r. = not relevant.
Additionally, the methods developed by Baas et al. (described in the preceding text) can be used for the detection of local inhomogeneities. It can now be decided on a case-to-case basis whether such inhomogeneities have any unwanted impact on the final analysis result.

The correction for neutron self-shielding in LSNAA may be made using information derived from the neutron fluence rate depression at positions in the irradiation facility just outside the sample. Overwater and Hoogenboom\(^{(42)}\) developed this approach to estimate the thermal neutron diffusion length \(L_s\) and the thermal neutron diffusion coefficient \(D_s\), which subsequently were used to reconstruct the neutron fluence rate profile inside the large sample. Both \(L_s\) and \(D_s\) are physical element properties and, similar to the effective linear \(\gamma\)-ray attenuation coefficient, boundaries can be estimated for the values of these two parameters in real materials. Though strongly correlated \((L_s^2 = D_s / \Sigma_a, \text{ with } \Sigma_a \text{ the macroscopic absorption cross section } (\text{cm}^{-1}))\), typical values are \(\sim 1 \text{ cm} < L_s < \sim 20 \text{ cm}\) and \(\sim 0.2 \text{ cm} < D_s < \sim 3 \text{ cm}\). An example is given in Figure 4. A \(\sim 1\)-m long, \(\sim 15\)-cm diameter water basin sediment drill core was analyzed in the frame of a pollution research project. Zinc foils were used as neutron flux monitors. The monitors were positioned just outside the sample container to monitor neutron fluence rate depression by comparison with the neutron fluence rates as monitored in a separate irradiation with a solid graphite sample, thus simulating the unperturbed neutron flux. The calculated values of \(L_s\) and \(D_s\) at different heights are plotted within the bandwidths for these values (Figure 11). Also, the average neutron fluence rates as a function of sample height is given. The fluence rates can be fitted with a cosine function, reflecting the flux distribution within the reactor's TC.

Assuring the quality of the results requires insight, monitoring, and control of the sources of error. Quality control procedures as traditionally applied in chemical analysis are not fully applicable in large sample analysis. One of the advantages of activation analysis is that some of the measured sample parameters dealing with \(\gamma\)-ray and neutron attenuation can only vary in ranges set by well-known values of elemental constants. These parameters can be much more easily determined in large sample analysis than with samples in the milligram range, thereby offering an outlook for direct verification of the quality of the related correction algorithms.

![Figure 9](image1.png) Figure 9  Range of linear \(\gamma\)-ray attenuation coefficients for typical materials.\(^{(50)}\)

![Figure 10](image2.png) Figure 10  Measured linear attenuation coefficients at 100, 300 and 1000 keV of a 15 cm thick soil drill core.
7 SENSITIVITY

Sensitivity is defined as the gradient of the response curve: i.e., the change in instrument response that corresponds to a change in analyte concentration. This definition translates in INAA into the net peak area as a function of the analyte mass. Larger peak areas at a given sample mass can be obtained by the following:

- higher neutron fluxes and longer irradiation times
- more efficient detectors
- larger sample masses.

Higher neutron fluxes and longer irradiation times are often not easily attainable, as the first is limited by reactor design, whereas longer irradiation times only have a positive effect on the sensitivity for radionuclides with very long half-lives.

Absolute photopeak efficiencies of detectors of different sizes and for different geometries are given in Table 7, and a comparison of the absolute efficiencies of a regular 17% coaxial and one of the largest well-type detectors reported in the literature\(^{51,52}\) is given in Figure 12. It should be noted that the use of Compton suppression shields does not result in an increase in sensitivity – as often erroneously suggested; after all, the signal resulting from the induced radioactivity does not increase and sometimes even decreases due to summing-out effects or larger sample-detector distances. Compton suppression systems find their advantage in a decrease in uncertainty of measurement due to decrease of the background under a peak.

Large sample masses can compensate for low neutron fluxes. As the limiting factor in NAA is merely the maximum acceptable induced radioactivity upon counting, a comparison has been made with normal INAA in which a hypothetical 200-mg sample is irradiated for a given time at a neutron flux of \(10^{13} \text{ cm}^{-2} \text{s}^{-1}\). Assuming a certain neutron fluence rate and a cylindrical sample of similar length and diameter, and an average density of 0.5 \(\text{g cm}^{-3}\), a first estimate can be made of the minimum...
mass needed to reach the same sensitivity as for the small sample at a high neutron fluence rate (Table 8). However, these results must be corrected for the losses due to neutron self-shielding and γ-ray self-attenuation, and the fact that the center of voluminous samples, simply for physical reasons, is always positioned further away from the detector than in case of a small sample. In Figure 13 these effects have been combined, and it can be derived that at a given neutron fluence rate a net gain in signal of a factor of 10 can be obtained by increasing the sample mass by a factor of 15 (e.g., from 200 mg to 3 g).

### 7.1 Natural Background

A large sample NAA procedure should start with measurement of the natural radioactivity of the sample, as the corresponding peaks in the γ-ray spectrum should be separately treated later on in the neutron and γ-ray self-attenuation corrections.

### 8 APPLICATIONS

LSNAA has evolved over the years towards a capability for various samples types that otherwise would have been difficult to analyze. Accordingly, the developments faced many challenges, each one different from the other, and in this process its horizon of application to various fields has increased: e.g., nutritional studies, geology, biology, archaeology, waste analysis, high-purity material characterization, precious samples, and liquid samples, from all walks of life. A few of them are given in the following text.

#### 8.1 Materials Difficult to Homogenize: Geological Samples, Ores, and Waste

LSNAA is highly suitable for the analysis of heterogeneous geological material such as rocks, coal (determination of quality), ores, and mineral concentrates. Conveyor belt monitoring of elemental concentrations by PGNAA in coal and cement raw materials has lead to an increased efficiency of coal-fired power plants and cement factories. It appears that this technique has the required potential to trigger industrial processes and gives reliable results.

Waste material in many cases is considered to contain hazardous substances whose behavior could result in their entry into biosphere through the atmosphere or ground water. Therefore, appropriate classification of the waste material is required in order to ensure safe disposal or further treatment and recycling. Construction material, domestic and electronic waste, as well as contaminated sediment and compost material are considered to be highly heterogeneous and therefore elaborate sampling procedures are required if representative sampling of these materials for analysis is needed. LSNAA has been effectively used to analyze large samples of soil,\(^{(53)}\) electronic waste,\(^{(54,55)}\) and other materials. These are the materials in which both subsampling and homogenization, steps not required in LSNAA, are very difficult and cost intensive. A typical example is the elemental composition analysis of waste from an incineration plant. This type of

sample cannot be easily homogenized and analyzed by other analytical techniques. However, a 1-kg portion of this waste was analyzed by using the LSNAA without homogenization.

8.2 Materials That May be Contaminated During Homogenization: High-Purity Materials

LSNAA is an extremely useful technique to analyze the metals and alloys for impurities. It is being used to analyze various finished products of alloys (Zircaloy 2, Zircaloy 4, SS-316M (stainless steel), and 1S aluminum) that are used in reactor technology\(^{(56)}\) and for impurities in high technological materials such as silicon and superalloys\(^{(53)}\). The biggest advantage is that information is obtained on the entire specimen, and because of the absence of subsampling, contamination can be minimized.

8.3 Materials Difficult to Subsample: Nutritional Studies

LSNAA is extremely useful in the determination of major, minor, and trace elements in foodstuffs, as large samples can be analyzed without resorting to subsampling. In fact, comparison of the results obtained from subsamples of varying mass gave an indication that a sample of 1 kg of wheat is more representative than small samples in the range of 40–1000 mg\(^{(57)}\). It is also feasible to determine trace elements in liquid diets, e.g., juices and milk, by LSNAA.

8.4 Valuable Material of Irregular Shape

Subsampling of archaeological and cultural heritage objects is generally prohibited, as these objects have to be preserved intact. LSNAA has the capability for nondestructive bulk analysis of the whole object. In comparison, other established nondestructive analytical methods, such as XRF or analytical techniques based on charged particle irradiation (PIXE, particle induced X-ray emission, IBA, ion beam analysis), can only analyze superficial layers of the sample and provide limited information over the whole volume of the object of interest\(^{(58,59)}\).

The particular advantage of INAA being noninvasive and a true multielemental technique is combined in LSNAA with the ability to analyze bulky objects as a whole, without any visual damage to the valuable cultural heritage objects. Art historians, conservators, and museum staff do not generally allow damaging such valuable objects by removing a portion for analytical purposes. However, sometimes only the elemental composition can decisively distinguish whether an object is different from what it appears to be from visual inspection.

8.5 Other Applications

Direct analysis of large samples provides a unique opportunity for (the validation of) (sub)sampling studies.

References 14

The activity and localization of a small-sized radioactive source in a large medium was studied for various cases by the simultaneous use of several detectors. The γ-emitting source and the neutron-emitting source were both studied. This also led to an α-emitting source, which cannot be detected from outside of the medium unless the neutrons from their (α, n) reaction with low Z elements are detected. A special actual case of commercial lung counter with four semiplanar HPGe detectors is described in detail. For large boxes, NaI(Tl) detectors were used for γ measurements measuring only the full-energy peaks. For neutrons, only thermal neutrons were measured with 3He detectors. To increase the fraction of the thermal neutrons and to protect the measurer, the sample was surrounded by a fence made of 5-cm polypropylene.

1 INTRODUCTION

Many measurements of radioactivity involve counting of γ rays or neutrons emitted by bulky samples, which are referred to as a box. While it is simple experimentally in the case of a point source in a known position, to transform the measurements of count-rate to activity (disintegration per unit time) and hence to the number of radioactive atoms, the problem can be the inaccuracy in the case of a small source in an unknown position in a bulky medium.

The inaccuracy is because of two factors: (i) the self-absorption and scattering of the photons in the sample and (ii) the unknown solid angle in which the detector sees the point source. Thus, in the case of a radioactive small source in an unknown position in a large box, we need to find its position in order to transform the count-rate to activity (see Instrumental Neutron Activation Analysis).

The measurements are different if the source is emitting γ rays or neutrons. In the case of the γ-emitting source, measurements can be done only for the photons that do not interact with the media surrounding the source, except for the media of the detector, by measuring the full-energy peak. In the case of neutron emission, the measurement of the spectrum of the emission is more difficult. In addition, most of the emitted neutrons are fast neutrons, while most of the detectors are more sensitive to thermal neutrons; hence, for better statistics, the neutrons are measured after their interaction with the surrounding material.

The localization of the source can be done only by measurement with more than one detector. The simple case is when it is known that the source in on a given line. In this case, there are only two unknowns: the activity and the location on the line; and two detectors on parallel faces of the box, collinear with the source, are sufficient. However, in the general case, there are four unknowns: activity and the three coordinates in space; then, at least four detectors are needed.

2 γ-EMITTING SOURCE

2.1 Two Collinear Detectors

2.1.1 Nonabsorbing Media

Two causes factor the decrease in efficiency with the increase in distance from the detector: (i) the isotropic propagation of γ rays, which leads to a smaller solid angle in which the detector sees the source with the increasing distance, i.e. the 1/distance^2 law and (ii) the absorption of γ rays inside the sample, i.e. the exp(−μ· distance) law. In order to separate these factors and dealing with only the first factor, a relative nonabsorbing media should be used. This can be done either with a low dense sample or, in the case of a low value of μ, the linear absorption coefficient, with high-energy γ rays. (1)

The mathematical treatment uses the assumption of the “virtual point detector” model for the voluminous γ detectors. (2–9) The bulky detector is treated as a virtual point detector on the symmetry axis of the detector at a distance d from the cap. This means that the count-rate in the absence of an absorbing/scattering medium due to a radioactive source at a distance y from the detector cap C(y) is given by the equation C(y) = C(0)/y^2, where d is...
the distance from the detector cap to the virtual detector point, \( y \) is the distance from the source to the detector cap, and \( C(0) \) is the count-rate measured on the detector cap.

The localization of the radioactive point source is done by two detectors on parallel faces of the box, collinear with the source, as shown in Figure 1. In Figure 1, \( d_{j1} \) is the distance between the inner face of the box and the detector \( j \) cap and \( d_{j2} \) is the distance between the detector cap and its effective virtual point detector; thus, if \( d_j = d_{j1} + d_{j2} \), we get the equation for the count-rate because of a source at a distance \( y \) from the inner face of the box.

\[
C_j(y) = \frac{C_j(0) \cdot d_j^2}{(y + d_j)^2} \quad j = 1, 2 \tag{1}
\]

For a point source at the center of a box with a linear dimension \( 2a \) (on the line of centers), this equation leads to

\[
C_j(\text{center}) = \frac{C_j(0) \cdot d_j^2}{(a + d_j)^2} \quad j = 1, 2 \tag{2}
\]

For a point source located at a distance \( x \) from the center, the distances from the box faces are \( a + x \) and \( a - x \), and hence Equation (2) yields

\[
C_j(x) = \frac{C_j(0) \cdot d_j^2}{(a + x + d_j)^2}; \quad C_j(\bar{x}) = \frac{C_j(0) \cdot d_j^2}{(a - x + d_j)^2} \tag{3}
\]

The normalized count-rate (normalized to the count-rate at the center of the box) \( N_1(x) \) and \( N_2(x) \) are

\[
N_1(x) = \frac{(a + d_1)^2}{(a + x + d_1)^2}; \quad N_2(x) = \frac{(a + d_2)^2}{(a - x + d_2)^2} \tag{4}
\]

Since both detectors are quite similar, we can accurately approximate \( d_1 = d_2 \). Equation (4) shows that, if we take the square roots of the reciprocal count-rate, the denominators are the same, while in the numerators, \( x \) appears once with a plus sign and once with a minus sign, which means that adding them cancels the terms with \( x \):

\[
\frac{1}{\sqrt{N_1}} + \frac{1}{\sqrt{N_2}} = 2 \tag{5}
\]

This sum has the units \( s^{0.5} \cdot \text{count}^{-0.5} \) and hence the square of its reciprocal value has the units counts per second, which are the units of count-rate. The definition of a new mean according to this equation, the harmonic mean of the square roots, leads to a mean that is independent of the position of the source.

\[
M_{\text{SH}} = \frac{2}{\frac{1}{\sqrt{N_1}} + \frac{1}{\sqrt{N_2}}} \Rightarrow M_{\text{SH}} = \frac{4}{\left(\frac{1}{\sqrt{N_1}} + \frac{1}{\sqrt{N_2}}\right)^2} \tag{6}
\]

Equation (5) indicates that \( M_{\text{SH}} \), defined for the normalized counts, should be equal to 1, independent of \( x \). It was found experimentally\(^1\) that the deviation of \( M_{\text{SH}} \) from 1 is always below 10% and, in most cases, not more than 2–3%.

This constancy of \( M_{\text{SH}} \) indicates the method of measuring the activity of a point source accurately within a box without having to know the position of the source. As we do not know the counts with the source at the center of the box, \( M_{\text{SH}} \) is not calculated with the normalized count-rates, but with the experimental ones. In this way, \( M_{\text{SH}} \) is independent of the position of the source, but dependent proportionally on the activity of the source. The box is calibrated for its efficiency by a standard point source with known activity, which is denoted by \( \text{Act(Std)} \), positioned anywhere on the line of the centers. Let us assign its mean square harmonic \( M_{\text{SH}} \) by \( M_{\text{SH}}(\text{Std}) \). The activity of any unknown source \( \text{Act(u)} \) of the same energy, positioned...
somewhere (unknown) on the line of centers, is given by

$$\text{Act}(u) = \frac{M_{\text{SH}}(u)}{M_{\text{SH}}(\text{Std})} \cdot \text{Act}(\text{Std}) \quad (7)$$

$M_{\text{SH}}$ is calculated from the count-rates of the two detectors (Equation 6). As the unknown source cannot be removed for the measurement of the standard source, the counts due to the standard source for each detector are calculated by the subtraction of two counts; one with the unknown source alone and the other with both of the two, the unknown source and the standard one.

If the exact place of the source in the box is required, the position of the source can be found from the ratio of the count-rates of the two detectors. From Equation (5):

$$R = \sqrt{\frac{N_1}{N_2}} = \frac{(d + a + x)}{(d + a - x)}$$

and hence

$$x = (d + a) \cdot \frac{1 - R}{1 + R}$$

where $x$ is the distance from the center of the box toward detector 2. Care should be taken to include $d$, besides the distance of the virtual point detector from the detector cap (which depends on the $\gamma$-ray energy) and also the thickness of the box and the distance of the outer face of the box from the detector cap.

2.1.1.1 Calculated Error for Longitudinal Sources The calculation till now assumes that the source is a very small one, close to a point. In the following, we calculate the error induced by a longitudinal source of length $2b$ lying on the line of centers with its midpoint coinciding with the midpoint of the line of centers (Figure 2).

The activity of an infinitesimal piece of the source with length $dx$ is $A \cdot dx/2b$, where $A$ is the total activity of the source. The normalized count-rates of the longitudinal source–detector (normalized to the whole activity being concentrated in the center) is given by the following integral

$$N = \frac{A}{2b} \int_{0}^{2b} \frac{dx}{(d + a - b + x)^2} \frac{A/d + a}{A/d + a}$$

Figure 2  Longitudinal measuring geometry.

By integration, the normalized count-rates are

$$N = \frac{(d + a)^2}{(d + a)^2 - b^2} = \frac{1}{1 - [b/(d + a)]^2}$$

(10)

If $b/(d + a) \ll 1$, $N$ can be approximated as $N = 2b/(d + a)$; this is the fractional error because the source is not a point source. As long as $b/(d + a) < 0.3$, the error due to a longitudinal source (Equation 10) is less than 10%.

2.1.2 Absorbing Media – Parallel $\gamma$ Lines

2.1.2.1 Activity Calculation The use of collimated detectors to measure only parallel photons, as, for example, in a medical double-headed $\gamma$ camera, eliminates the decrease in the solid angle in which the detector sees the source with the increase in the source–detector distance and leaves the effect of the source–detector distance to the sole effect of absorption/scattering. In this case, the geometric mean of the count-rate of the two detectors can be used to calculate the activity of the unknown source:

$$C_1 = C_{10} \cdot e^{-\mu(a-x)}; \quad C_2 = C_{20} \cdot e^{-\mu(a+x)}$$

(11)

From Equation (11), the geometric mean of the two counts measured by the two detectors is given by

$$M_G(x) = \sqrt{C_1(x) \cdot C_2(x)} = \sqrt{C_{10} \cdot C_{20} \cdot e^{-2\mu a}} = e^{-\mu a} \sqrt{C_{10} \cdot C_{20}}$$

(12)

Equation (12) shows that the geometric mean of the two count-rates is independent of the position of the point source but depends linearly on the activity of the source. Thus, the geometric mean can be used to measure the activity of an unknown source using a calibrated source positioned on one of the faces of the box between the detector and the box:

$$\text{Act}(u) = \frac{M_G(u)}{M_G(\text{Std})} \cdot \text{Act}(\text{Std})$$

(13)

2.1.2.2 The Error due to a Longitudinal Source The mathematical approach described previously assumed that the active source is very thin. In the following, the error is induced if the source has a dimension in the plane of the detectors. Let us assume that the whole activity is spread over a length $b$ (Figure 2). Then, the count-rates due to infinitesimal length $dx$, assuming there is no absorption by the medium, are $\frac{C_{10}}{b} dx$ and $\frac{C_{20}}{b} dx$. The
count-rates due to the absorption effects are (Figure 3):
\[ C_1 = \frac{C_{01}}{b} \int_0^b e^{-\mu(x+d)} \, dx = \frac{C_{01}}{\mu b} e^{-\mu d} \cdot (1 - e^{-\mu b}) \]
\[ C_2 = \frac{C_{02}}{b} \int_0^b e^{-\mu[2a-(x+d)]} \, dx = \frac{C_{02}}{\mu b} e^{-\mu 2a} \cdot e^{\mu d} (e^{\mu b} - 1) \]

where \( 2a \) is thickness of the box, \( d \) is the distance of one side of the source from one of the detectors, and \( x \) is the distance of the infinitesimal length \( dx \) from the same side of the source. The geometric mean is
\[ M_G = \sqrt{C_1 \cdot C_2} = e^{-\mu d} \sqrt{C_{01} \cdot C_{02}} \sqrt{(1 - e^{-\mu b})(e^{\mu b} - 1) / \mu b} \]

The correction factor \( K \) due to the dimension \( b \) perpendicular to the detector’s plane is given by
\[ K = \frac{\sqrt{(1 - e^{-\mu b})(e^{\mu b} - 1)}}{\mu b} \Rightarrow K = \frac{e^{\mu b / 2} (1 - e^{-\mu b})}{\mu b} \]

As long as \( \mu b < 1.5 \), the error is \(<10\% \) \((K < 1.10)\). For example, for \(^{99m}\)Tc in water \( \mu = 0.152 \, \text{cm}^{-1} \), then for an object with size \(<10 \, \text{cm} \), the error is \(<10\% \).

2.1.2.3 Source Localization The previous mathematical model yields the activity of the unknown source in the box without knowing where the activity is located. However, the location of the source can also be calculated using Equation (11). Dividing the two, Equation (11) yields
\[ R(x) = \frac{C_1(x)}{C_2(x)} = \left[ \frac{C_{10}}{C_{20}} \right] \cdot e^{\mu 2x} \]
\[ x = \ln[R(x)/(C_{10}/C_{20})] \]

If the two detectors are equal, or are made to give equal responses by adding a factor to one of them, then \( C_{10}/C_{20} = 1 \).

If the material in the box is known, Equation (15) can be used for calculating \( x \) from the known \( \mu \). However, in case the content of the box is unknown, \( \mu \) can also be calculated from the measurement of the external calibrated standard on the face of the box by the two detectors, as the only decrease in the counts is due to the absorption.
\[ \mu = \frac{\ln[R(\alpha)]}{2a} \]

Here, \( R(\alpha) \) is the ratio of the two count-rates due to the external source alone.

2.1.3 The General Case

The general case is where both, the solid angle in which the detector sees the source and the absorption/scattering, are operational.

2.1.3.1 Activity Calculation In the previous sections, it was shown that, when only the solid angle is important, the activity can be calculated from the square root harmonic average, while when only absorption is operational the geometric average is the right method to calculate the activity. Since these two effects are independent, it can be expected that, in the general case, the right answer is a weighted product of these two averages. The weighing must ensure that the units of the new average are the same as count-rate\(^{(10)}\):
\[ M_{GSH} = M_{SH} a \cdot M_G 1-a \]

It was found that \( \alpha \) depends on the contents of the box\(^{(10)}\) and \( \alpha \) can be found from the measurement of the count-rates at several points of the box. However, for an unknown box, this means opening the box or reproducing a similar box for calculating \( \alpha \). The method to measure the radioactivity in the box without the need to open it is by previous localization of the radioactive point source, as discussed in the next paragraph.

2.1.3.2 Localization of the Point Source It was shown\(^{(11)}\) that the count-rate of a detector positioned on the face of a box as a function of the distance of a point source, positioned inside the box filled with polypropylene, from the detector is close to exponential dependence, but is not very accurate. The exponential dependence on the distance from the box’s face is improved if, instead of taking the count-rate of one detector, the ratio of the count-rates of two detectors positioned on parallel faces is taken. Another possibility to improve the exponential dependence is to position the detector at a distance from the face of the box. However, increasing the distance between the detector and the box leads to worse statistics because of a smaller count-rate. In addition, the use of the ratio of the count-rates of two detectors is preferable as the equation of the count-rate \( C(x) \) versus the distance of the source from the box face \( -x \),
\[ C(x) = C(0) \cdot e^{-\mu x} \]

has two parameters, \( C(0) \) and \( \mu \), which require at least two calibration experiments. Performing two calibration measurements is difficult if we do not want to open the box. On the other hand, if the two detectors are equal, or made to be equal, by adding a factor to one of them,
the two parameters of the equation of the ratio of the count-rates
\[ R(x) = R(0) \cdot e^{-\mu x} \]  
(21)
can be shown to be correlated, leading to only one parameter.

If the length of the box is \( a \), then \( R(0) \) and \( R(a) \) are reciprocal numbers, as changing from 0 to \( a \) means replacing the detectors. Substituting \( R(a) = 1/R(0) \) yields
\[ R(0) = a^\mu /a^2 \]  
(22)

Hence
\[ x = -\frac{a}{2} \left( 1 - \frac{\ln[R(x)]}{\ln[R(0)]} \right) \]  
(23)

The activity of the source cannot be calculated from the ratio of the count-rates as \( R(x) \) is independent of the source activity. For the determination of the source activity, the measurement of the count-rate of one detector must be used, together with the calculated \( x \) from Equation (23). Since in the case of the detectors close to the box, the dependence of the count-rate on the distance \( x \) is quite complex, it is preferable to use measurements at a distance between the detectors and the box. As mentioned before, there are two unknowns, \( C(0) \) and \( \mu \), but \( \mu \) for one detector measurement can also be deduced from the measurements of the ratio of the count-rates at the same distance detector box. It was shown earlier that \( \mu \) for the expression \( R(x) \) can be found from \( R(0) \) and the box length. The \( \mu \) for one detector count-rate was proven to be one-half of the \( \mu \) for the ratio of the count-rates.\(^{11}\)

2.2 Four Detectors

Old lung counters were made of two large-sized phoswich detectors. In order to increase the resolution of modern lung counters, semi-planar Ge detectors were used. Owing to the small size of the available Ge detectors, 3 or 4 detectors were typically used to cover the area of the two lungs previously covered by two phoswich detectors.\(^{12,13}\) A commercially available set of four detectors is the Lung-Counter composed of four semiplanar HPGe detectors that were positioned two on each lung on the chest.

2.2.1 Lung Detector

The basic assumption generally made when calibrating a lung counter is that the deposition of the radioactive aerosols in lungs is homogenous; however, it has been reported that the distribution is a function of the aerosol size and the breathing rate and changes with time.\(^{14}\) In some cases, the contamination can be present in the form of a single “hot” particle. The count-rate of an external detector is strongly dependent on the position of the “hot particle”; the possible errors in activity determination due to deviations from homogeneity were evaluated to be factors of 26, 3, and 1.8 for photon energies of 17, 60, and 1000 keV respectively.\(^{15}\) and factors of up to 20 were measured for natural uranium.\(^{16}\) The extra information due to more than one detector allows the localization of a point source in the lungs.

2.2.1.1 The Mathematical Method

The mathematical method used is applicable not only for localization of radioactive sources but also for any technique using several measurements to identify an unknown.\(^{17}\) The most well known analysis using this mathematical method is the identification of an analyte from its electron-impact mass spectrum (EIMS).\(^{18}\) but the method can be also used for source identification.\(^{19–21}\) It is based on a calibration with a radioactive point source positioned consecutively in various locations in a phantom, which is the actual bulky material. For every positioning, the four detectors measure the pulse height spectra, and the count-rate for each \( \gamma \) full-energy peak is then calculated. The position of an unknown radioactive point source can be found by comparing its count-rates measured by the four detectors with similar data obtained for each of the various locations during the calibration. The mathematical problem is to find which of the sets of the standards (which, in our case, contain the results of the four detectors) best fits the four count-rates of the unknown.

The values of the count-rates of the four detectors are set as the components of a vector and all the vectors are normalized to unity length.\(^{22}\) Each normalized vector can be seen as a single point on a hypersphere with a unity radius in an \( n \)-dimensional hyperspace, where \( n \) is the number of the vector components (the number of the detectors). If two vectors (points on the \( n \)-dimensional hypersphere) are identical in all the components, there will be a perfect “match” that represents the same point in the hyperspace. However, because of instrumental instability and the statistical nature of the measurements, the point of an unknown coincides exactly with one of the points in the library of standards only rarely. Actually, even repeating the same measurement at the same point rarely gives exactly the same count-rates. The problem of finding the best match for the vector of an unknown in the library of the vectors of standards can be solved in principle by two methods (two matching factors). The first method can be described as the “nearest-neighbor” technique, while the second can be defined as the “minimal contact angle”, although, in many cases, it is called the dot product method after the mathematical operation used to calculate the angle.
The first method calculates the distances between the head of the vector of the unknown and the heads of each of the vectors of the standards (the library), looking for the minimum distance, i.e. the minimum of
\[ \Delta_j = \sum_{i=1}^{n} (u_i - s_{i,j})^2 \]  
where \( u_i \) is the \( i \)th component (the detector \( i \)) of the vector of the count-rates of the unknown and \( s_{i,j} \) represents the \( i \)th component of the \( j \)th vector in the library of standards. The summation is performed over all the components of the vector (all the detectors). It should be emphasized that all the vectors must be normalized (to be of unity length) in order to compensate for different activities of the standard and the unknown:
\[ u_i = \frac{U_i}{\sum_{k=1}^{n} U_k}; \quad s_{i,j} = \frac{S_{i,j}}{\sum_{k=1}^{n} S_{k,j}} \]

where \( U \) and \( S \) are the original un-normalized vectors.

In the second method, the angles between the unknown vector and each of the standard vectors are calculated. The cosine of the angle between two vectors can be calculated from the values of their components by using the scalar “dot product”:
\[ \cos \theta_j = \frac{s_j \cdot u}{|s_j| \cdot |u|} = \frac{\sum_{i=1}^{n} s_{i,j} \cdot u_i}{\sqrt{\sum_{i=1}^{n} s_{i,j}^2 \cdot \sum_{i=1}^{n} u_i^2}} \]

The summation is done over all the components of the two vectors (which are of the same dimension). Actually, the calculation of the angle does not require the normalization of the vectors and can be performed on the original data:
\[ \cos \theta_j = \frac{S_j \cdot U}{|S_j| \cdot |U|} = \frac{\sum_{i=1}^{n} S_{i,j} \cdot U_i}{\sqrt{\sum_{i=1}^{n} S_{i,j}^2 \cdot \sum_{i=1}^{n} U_i^2}} \]

However, it is preferable to use the normalized vectors at least for all the standards. Even if the vectors are not normalized explicitly, normalization is still performed in the process of calculating the lengths of the vectors in the denominator of Equation (27), which includes division by the lengths of the vectors. It is better to calculate the lengths only once in the normalization process rather than to calculate them for each unknown.

Lengths of normalized vectors are unities, which simplifies Equation (26):
\[ \cos \theta_j = \frac{s_j \cdot u}{|s_j| \cdot |u|} = \sum_{i=1}^{n} s_{i,j} \cdot u_i \]  

The Experimental System
The measurements were performed by the NRC-Negev lung counter system, which consists of four semiplanar HPGe detectors measuring a uranium source inside a phantom, as can be seen in Figure 3. The information from each detector was analyzed separately by a multichannel analyzer. The uranium source was a sealed cylinder with a radius of 1.5 mm and length of 5 mm, which contained natural uranium (99.27% \( ^{238}\text{U} \) and 0.72% \( ^{235}\text{U} \)) with an activity of 1.85 kBq. The main \( \gamma \) lines were 92 keV because of the \( ^{238}\text{U} \) chain (due to \( ^{234}\text{Th} \)) and 186 keV mainly because of \( ^{235}\text{U} \). The quantitative information from each measurement was the count-rates of the 186 and 92 keV peaks (the areas under the peaks divided by the counting time). Other \( \gamma \) peaks were also observed; however, their counts were smaller, implying larger statistical errors, and they were not used in the analysis.

The detectors were calibrated using a realistic phantom designed by Lawrence Livermore National Laboratory. The phantom lungs used were made of tissue-equivalent plastic material and had 28 cylindrical holes, where point sources of natural uranium could be placed, as can be seen in Figure 4. All holes were normally filled with cylinders made of the same tissue-equivalent plastic as the lungs, and a small portion of the cylindrical filling was replaced by the source only at the checked position, so that the absorbing properties of the lungs remained practically unchanged and fully simulated the human lungs. The 56 points for placing the sources at different locations (two points in each hole) were distributed all over the lungs. Twenty-eight points were located on the upper surface of the lungs and 28 on the lower surface.
The matching factors ($\Delta_j$ and $\cos \theta_j$) of the counts for the source placed at an unknown position with each of the 56 different points of the library data base were calculated. On the basis of the minimum value of $\Delta_j$, the matching factor, or a maximum of $\cos \theta_j$, the other matching factor, a “predicted point” was determined and compared with the actual point location. If there was a match between them, it was called a success or just a hit.

The difference between the calculated and the actual activity (the error in calculation of the activity) was calculated as follows. After determination of the actual activity (the error in calculation of the activity) because, in the “nonhit” cases, the resulted position was the known source activity was the error for the specific measurement.

There was a one-to-one correlation between $\cos \theta$ ($\theta$ stands for the angle between the two vectors) and the distance between the points (heads of the vectors) in the hyperspace, and it was found, in the case of localization of a radioactive point source in the lung phantom, that Equations (3) and (5) actually gave the same results.\(^{(19)}\)

The Use of Weighted Results  Stein\(^{(23)}\) found that the identification in EIMS gets better if, instead of raw ion intensities, the values (ion intensity $\cdot$ ion mass)\(^{1/2}\) are taken as the components of the vectors. This choice of components of the vectors increases the weights of low-intensity peaks produced by ions of big masses.

In our case of the lung phantom, it was also found that the number of “hits” increased slightly if raw values of the count-rates were multiplied by weighing factors. The various weighing factors studied are given in Table 1. For calculation of the least distance, it was found that the best results were obtained for weights taken as the reciprocal of the mean of the normalized count-rates of the unknown and the library vectors. The raw vectors are first normalized, and the weights are calculated from the normalized vectors. In a mathematical notation, this means that, instead of searching for the library vector $\mathbf{L}$ that leads to the minimal values of $\sqrt{\sum_{i=1}^{n}(\mathbf{L}_j - \mathbf{U}_i)^2}$ for the various vectors of the library (where $\mathbf{U}$ is the vector of the unknown), we are looking for the vector $\mathbf{L}$ that yields a minimal value of $\sum_{i=1}^{n} (\mathbf{U}_j - \mathbf{L}_i)^2 / (\mathbf{U}_j + \mathbf{L}_i)$. Because we are looking for the minimal distance, this assigns bigger weights to the measurements of larger counts with smaller statistical errors. When these weights are used, the fraction of the “hits” (where “hit” means that the method detects the correct location of the source) increases from 78 to 82%.\(^{(19)}\) Although there were only 82% of “hits”, the mean error in the calculated activity was only 10.4% because, in the “nonhit” cases, the resulted position was

</table>

quite close to the real one, which led to a relatively small error in the calculated activity.

**Homogenous versus Point-wise Distribution**

Application of this method to a homogenously distributed source in the lungs of the phantom results in the best “fit” for one of the points in the center. The error in the activity is quite large in this case, almost 40%. It seems that this method can work only when applied to inhomogeneously distributed radioactive contaminants. However, this problem can be solved by adding another vector to the set of the standards.\(^{24}\) This vector is the response of the four detectors to a phantom with homogenously distributed radionuclides, which can be defined as a “virtual point”. Another possibility for a vector representing the homogenously distributed lungs is to take the arithmetic mean of the 56 calibrating points for each one of the four detectors. With this extended set of standards, the “guessed point” for homogenously distributed lungs is taken at the arithmetic mean of the 56 calibrating points for each one of the four detectors. With this extended set of standards, the “guessed point” for homogenously distributed lungs is always found in this virtual vector, and the error in the calculated activity is below 5%. Thus, one can actually distinguish between a homogenous distribution and a point location.

**Simultaneous use of two γ lines**

In the case of uranium contamination, the count-rates of two relatively strong γ lines were measured by the four detectors, namely, the lines at 92 and 186 keV. The 92-keV line is due to a daughter in the \(^{238}\)U chain, while the 186 keV line originates mainly from \(^{235}\)U. These γ lines, when used separately, provide approximately the same fraction of “hits” and the same mean error in the activity, but a closer observation shows that the cases of “nonhits” are not the same for both the lines. This is reasonable because the main cause for a “miss” is the statistical nature of the count-rates. It was found\(^{20}\) that analyzing the two energy peaks together could provide better results. Eight-component vectors were composed. Out of these, four components were the 92 keV count-rates measured by the four detectors, while the other four components were count-rates measured by the same detectors for the 186 keV line. The normalization of the vectors involved all the eight components. It can be seen in Table 2 that the fraction of “hits” increased from 82%, when each of the energies was analyzed separately, to 94%, when the two energies were analyzed together using an eight-dimensional vector. The mean error in the activity decreased from 10.4 to 3.8%.

Table 2 gives the percentage of “hits” and the error in the calculated activity for four detectors, both for using only the count-rates at either the 186 or the 92 keV peak (vectors of four dimensions) and the simultaneous count-rates at the 92 and the 186 keV peaks (eight-dimensional vectors). In the case of Table 2, the library was built from all the 224 experiments, and each standard vector was the average of four repeated experiments. The unknown vector was one of the 224 vectors, leading to the same vectors being used as part of the library, although in an average with three other experiments and as the unknown. In Table 3, the same results are given when the average of only two repeating experiments (112 measurements) was used to calculate the library, while
the other 112 measurements were treated as unknowns. There are six possibilities (\(C_2^4\)) to choose the two repeating experiments used for the library; the results in Table 3 are the average of these six possibilities.

However, using the two \(\gamma\) lines presents a problem when the isotopic composition of the uranium in the calibration standards is different from that of the unknown, because the two lines are produced by different isotopes. It was shown\(^{(21)}\) that, if the isotopic compositions were different, errors in localizing a source and determining its activity were larger with the eight-dimensional vector than with the four-dimensional one. This study\(^{(21)}\) shows that, in such a case, the method of simultaneous analysis of two \(\gamma\) energy peaks leading to eight-dimensional vectors can still be used to improve the accuracy, but the eight-dimensional vectors should be normalized in an unusual way, which can be called \textit{double half-normalization}. In this method, the four counts of each \(\gamma\) energy are normalized separately. The components of the normalized vector \(c_j\) are

\[
c_j = \frac{C_{92,j}}{\sqrt{4 \sum_{k=1}^{4} C_{92,k}}} ; \quad \text{for } j = 1 - 4
\]

\[
c_j = \frac{C_{186,j+4}}{\sqrt{4 \sum_{k=1}^{4} C_{186,k}}} ; \quad \text{for } j = 5 - 8
\]

In the expressions above, the measured count-rates are \(C_{92,j}\) and \(C_{186,j}\), where \(j = 1 - 4\) represent the four different detectors. Pelled\(^{(21)}\) found that this complex normalization (the lengths of the vectors are actually 2) decreases the fraction of “hits” in the case of the same isotopic composition only from 94 to 93%, which is still much higher than the success rate when a single \(\gamma\) line in used. When the isotopic compositions are different, this larger dimensionality increases the fraction of “hits” almost to the same degree as in the case of the same isotopic composition. However, when the isotopic compositions are extremely different, the statistics of one of the energy lines is expected to be poor; therefore, it is better to use only the most abundant \(\gamma\) line.

**Detectors at the Back**  
Another way to increase the dimensionality of the vectors is to use more detectors. In practice, the four detectors cover most of the area of the lungs, and, physically, there is no place for additional ones. However, they can be mounted on the back of the phantom. Counts by detectors mounted on the back are usually lower due to stronger absorption of the photons. Hence, longer counting times are required to get good statistics. Count-rates for the normal counting time with the detectors positioned at the back of the phantom were studied,\(^{(24)}\) thus simulating an array of eight detectors. The results can be represented by eight-dimensional vectors or 16-dimensional vectors if both the \(\gamma\) energies (92 and 186 keV) are used. The percentage of “hits” exceeded 99%, suggesting that placing lung detectors behind the phantom, by mounting them in a chair support, is worthwhile. There is actually no need for eight detectors as only two additional detectors at the back increase the fraction of “hits” to about 99%.

**Table 3**  
Average results obtained when either the 186 or the 92 keV peaks were used separately and when both peaks were used simultaneously, using all six library combinations of 112 measurements

</table>

Possibly more interesting results of this study are that, even when only four detectors are used, it is considerably better to locate one or two of them at the back.\textsuperscript{241} Tables 4 and 5 yield the percentage of “hits” and the error of the calculated activity both for using the 186 keV peak alone and for the simultaneous use of the 92 and 186 keV peaks. Each line gives the results for another arrangement of the four detectors. The detectors in the front are assigned by A, B, C, and D, while the detectors at the back are denoted by BA, BB, BC, and BD. Detector A is located opposite the upper part of the right lung. Detector B is located opposite the upper part of the left lung. Detector C is located opposite the lower part of the left lung, and detector D is located opposite the lower part of the right lung. When measuring very low energy γ photons, as, for example, when measuring contamination with $^{239}$Pu, the detectors at the back hardly see anything. However, Tables 4 and 5, in which each line giving a different arrangement of the four detectors shows that, even for natural uranium, with not very high energy photons, positioning of one or two, out of the four, detectors at the back leads to considerably more accurate results. This is clearer in the case of only one photon energy or if the library used were counted for a relatively short time (6 h in Table 5 compared to 12 h in Table 4).

3  NEUTRON SOURCES

The main difference between neutron sources and γ sources is that, while γ sources emit photons of discrete energies, mainly one or two major lines, the radionuclidic neutron source, both fission sources or ($α$, $n$) sources, emits a spectrum of neutrons, mainly fast ones with an average of more than 1 MeV. Another difference is that it is quite easy to measure the spectrum of the γ photons emitted from the box, and the resolution of the energy spectrum is quite high, while, on the other hand, measurement of the spectrum of the neutrons is quite a task, and the resolution of the energy spectrum is quite low. Taking these two differences and the much larger sensitivity of usual neutron detectors to thermal neutrons than to more energetic neutrons, it is almost impossible to measure only neutrons that reach the detectors without interaction with the box and the surrounding materials, as was done for γ photons. Not only the interaction with the box but also the interaction with the shield of the experimental system should be considered, as the detectors must be shielded from outside radiation and the researcher must be protected from the neutron irradiation. This shield, if made from hydrogen-containing material, not only shields the detector from outside
It was found due to reflection of thermal neutrons from the shielding, but also increases the count-rate at the detector due to reflection of thermal neutrons from the shielding material.

### 3.1 Two Neutron Detectors

It was found\(^{(25)}\) that, when two \(^{3}\)He detectors were positioned on two parallel faces of a box with a small neutron source in the box on the line connecting the two detectors, the ratio of the two count-rates was an exponential function of the distance between the source and one of these faces. The exponential dependence was found to be independent of the medium in the box, from air to highly hydrogenated material, although the coefficient of the exponentiality depended on the medium. This is the same as that described earlier for two \(\gamma\) detectors in the general case and hence the same equation should apply:

\[
x = -\frac{a}{2} \left(1 - \frac{\ln[R(x)]}{\ln[R(0)]}\right)
\]  

(29)

where \(x\) is the distance from the box’s face, \(a\) is the length of the box (the distance between the two faces on which the detectors are positioned), and \(R\) is the measured ratio of the two count-rates. \(R(x)\) is the ratio for the unknown source and \(R(0)\) is the ratio for an external source positioned on the face of the box \((x = 0)\). It was found that Equation (29) yields quite accurate results, as can be seen in Table 6. In this table, \(\Delta x/a\) is the fractional error in the location. As can be seen in this table, the calculated location is quite accurate except for the cases where the source is positioned very close to one of the two faces of the box. This is probably due to thermal neutrons coming to the close detector only by scattering from the shielding, as the neutrons coming directly from the source are too energetic to react with the \(^{3}\)He in the detector. In order to get more accurate results, 5-cm polypropylene slabs were positioned between the detectors and the box.\(^{(26,27)}\)

### 3.2 More than Two Detectors

When the unknown neutron source is not on the line (actually a plane as the detectors are quite long) connecting the two detectors, it is found that Equation (29) gives the correct result only if \(R(0)\) is measured for the external source positioned on the face of the box in a plane parallel to the detectors’ plane but passes through the unknown source. Therefore, now the problem is to find this plane. Two solutions are found to this problem. In the first solution, three pairs of \(^{3}\)He

It is found that the pair that gives the highest geometric mean of the count-rates is the closest to the unknown source and hence the external source should be positioned in this plane. However, this still gives an error of one-sixth of the width of the box and, consequently, for larger boxes it will require more detectors. A better solution that requires only four detectors involves the moving of the external source on different faces by an iterative method. The iterative method was applied to localize the unknown neutron source by finding successive approximations to the solution, starting from an initial estimate regarding the unknown source plane ($y$ coordinate). First, the $x$ coordinate of the unknown source was calculated, using Equation (29), from the results of the two detectors on the $y$ axis (detectors 1 and 2, which are on parallel faces of the box, as can be seen in Figure 5). Both $R(x)$ and $R(0)$ were measured by detectors 1 and 2. Measurements were made of the unknown source alone and together with a known (calibrating) source placed outside the box; $R(0)$ was the difference between the two measurements. In this first step, $R(0)$ was measured with the known

performed after the initially estimated calculation of experimental results. For most points, two iterations were done by iterations. Table 7 presents, as an example, √ source position and the calculated one, accuracy.

Table 7 shows the various calculations of x and y done by iterations. Table 7 presents, as an example, the iteration calculations of row b (Figure 5) of the experimental results. For most points, two iterations were performed after the initially estimated calculation of x, until x or y recurred. It was found that one iteration (two consecutive calculations of y and x) after the initial estimate already yielded a major improvement to the accuracy.

Table 8 shows the distance between the real source position and the calculated one, \(\sqrt{(y_{\text{cald}} - y_{\text{real}})^2 + (x_{\text{cald}} - x_{\text{real}})^2}\) both for x and y calculated with central \(R(0)\) for both coordinates and the distances calculated after completing all the iterations. One to four iterations are required, depending on the source’s position. Iteration calculations reduce the average calculated distance between the real source position and the calculated one from 2.46 to 1 cm and reduce the maximal distance from above 10 to <4 cm.

Aerosols and Particulates Analysis: Indoor Air

Radu Branisteianu
Institute of Public Health, Iasi, Romania

1 Introduction

There is no doubt that exposure to indoor aerosols represents a cause of concern. Humans breathe the air no matter whether they work, eat, sleep or relax. The levels of contaminants in buildings depend on the type of activity and the number of inhabitants, but also on general economic development.

Traditionally, the studies dedicated to human exposure to airborne toxins contained within buildings focus separately on occupational and non-occupational environments. However, the enclosed spaces with human activity comprise either industrial or nonindustrial environments. Apart from the well-known differences, these two types of environment have in common a very important element: the human being. Therefore, IAQ represents in fact an integrated issue, as the two faces of the same coin.

The assessment of human exposure to indoor aerosols is a multidisciplinary action that includes the identification and quantitation of airborne toxins. In order to obtain representative and reliable analytical results, the comprehensive understanding of the physical, chemical and toxicological behavior of the aerosols is essential. The chemist should have all that information in order to choose the analytical method that gives the best cost/performance ratio in a particular application.

This article is intended to provide information and directions needed in the assessment of indoor aerosols, both in industrial and nonindustrial environments. It comprises brief considerations about the deposition of particulates in human airways, the characteristics of the particles and aerosol classification. Section 3 describes some widespread types of aerosols found in occupational and domestic environments. The characterization comprises considerations upon chemical composition, size, shape and the influence upon human health. Methods of analysis are also mentioned. Section 4 describes the factors that influence the sampling and storage of aerosols. Section 5 deals with applications of aerosol analysis in industrial hygiene. Sampling, sample preparation and analyse are exemplified on three selected compounds: metallic species, polycyclic aromatic hydrocarbons (PAHs) and silica. Alternative methods for specific applications are presented. Section 6 refers to home and office environments and approaches strategies used for indoor air quality (IAQ) assessment and the analysis of bioaerosols. Section 7 addresses the air standards and their influence upon analytical methodology and instrumentation. Section 8 comprises a brief discussion regarding differences encountered in aerosol analysis in industrial and nonindustrial environments.
knowledge, aerosol characteristics, sampling methodology and laboratory analysis. Regulations and conventions are also included.

2 FROM RESPIRATORY TOXICOLOGY TO INDUSTRIAL HYGIENE

2.1 Deposition of Particulates in Human Airways

Upon inhalation, particles are arrested and deposited differentially according to the location in the respiratory tract (RT). There are four main mechanisms that contribute to particle deposition in the human airways: interception, inertial impaction, gravitational sedimentation and radial diffusion. In the case of the first three mechanisms, the deposition efficiency increases with the increase of the particle diameter. With respect to radial diffusion, the deposition efficiency increases with the decrease of the particle diameter. The electrostatic attraction/repulsion is a mechanism that contributes to a lesser extent to the particle deposition in the human RT. Detailed description of these processes can be found in Lippmann, ICPR, and Rando.

The particle size represents the key parameter which influences deposition into the RT. The size of the particles that deposit due to the impaction and sedimentation mechanisms is described in terms of aerodynamic diameter, $d_{ae}$. The aerodynamic diameter is defined as the diameter of a unit density sphere having the same terminal settling velocity as the particle in question. For very small particles which deposit primarily by diffusion the size is described in terms of thermodynamic diameter, $d_{th}$. The $d_{th}$ is equivalent to the particle volume equivalent diameter. The transition from $d_{ae}$ to $d_{th}$ occurs in the region of 0.5–1 µm.

Figure 1 shows a typical pattern of particle deposition in human RT obtained by Freijer using computer simulation.

For the purpose of analysis, the RT is divided into five compartments, each representing a region. The stacked graph expresses the cumulative fraction into five compartments, each representing a region. The particle size represents the key parameter which influences deposition into the RT. The size of the particles that deposit due to the impaction and sedimentation mechanisms is described in terms of aerodynamic diameter, $d_{ae}$. The aerodynamic diameter is defined as the diameter of a unit density sphere having the same terminal settling velocity as the particle in question. For very small particles which deposit primarily by diffusion the size is described in terms of thermodynamic diameter, $d_{th}$. The $d_{th}$ is equivalent to the particle volume equivalent diameter. The transition from $d_{ae}$ to $d_{th}$ occurs in the region of 0.5–1 µm.

The $d_{th}$ is equivalent to the particle volume equivalent diameter. The transition from $d_{ae}$ to $d_{th}$ occurs in the region of 0.5–1 µm.

2.2 The Behavior of the Liquid Particle Aerosols

Aerosols having the disperse phase composed of liquid droplets exhibit a different behavior inside the human RT. After inhalation, liquid particles, which are very small, may reach all parts of the lung, from where they may be readily absorbed. The volatility of the material may also lead to concentrations that rise to values far above those possible from partial pressures of the gaseous phase at room temperature. This is the case of some solvents, for which the vapors are relatively harmless at ambient temperature but are hazardous when they exist as a mist.

2.3 Characteristics of Interest

Human exposure to indoor aerosols and particulates depends on a number of determinants pertaining to the nature of the contaminant, the characteristics of the confined space (e.g. microclimate, ventilation, etc.) and
the individual traits of the exposed subject. The physical and chemical properties of the aerosols influence their emission and behavior in the atmosphere, but also the deposition and uptake, once inhaled by humans. Some of these characteristics may be measured.

1. **Chemical composition.** The chemical composition of aerosols and particulate matter is the main determinant of toxicological interest. It reflects the action of toxins upon the living organisms and gives information about other properties of interest such as vapor pressure, solubility, and reactivity. Chemical composition influences the strategy of collection and analysis of aerosols.

2. **Mass.** The action of the toxins upon living organisms depends on both the quality and the quantity of the compounds. The amount of toxin in the air is quantified in terms of concentration, which, in most cases, represent the mass for a given volume of air (e.g. mg m\(^{-3}\)). In the case of aerosols, the concentration may refer to the entire quantity of particles present in the air or to a particular toxin previously quantified by chemical analysis.

3. **Number.** The number of particles is also a quantitative measurement. In the assessment of exposure to fibers the airborne concentration of particles is expressed in terms of number for a given volume of air (number m\(^{-3}\)). Sloff and Blokzijl\(^5\) mention that the number of fibers for a given quantity of dust (e.g. number ng\(^{-1}\)) may be sometimes encountered.

4. **Size.** Particle dimensions influence the behavior of a certain aerosol both in the surrounding atmosphere and inside the human RT. Smaller particles spend more time in the gaseous medium before they settle but penetrate deeper into the lung compartments.

5. **Shape.** The shape of the particulates influences their aerodynamic behavior. The ratio length: diameter constitutes a criterion for the counting rules employed in fiber exposure assessment.

6. **Surface properties.** In some cases, the level of biological activity is strongly influenced by the surface properties of particulates (e.g. adsorption capacity, hydrophilicity, surface radicals, defects, surface impurities). These characteristics cannot be determined by chemical analysis of bulk samples nor by conventional microscopy, and surface analysis must be performed.

7. **Vapor pressure.** Apparently, vapor pressure is a characteristic with low implication in aerosol assessment. However, it determines the saturated vapor concentration in air. At concentrations above this value, a less volatile material will partition between the vapor phase and the aerosol (condensed) phase. In addition, the adsorption of very volatile pulmonary irritants onto particulates may increase their injury potential for the deeper parts of RT since the cleanup action of the upper airways is bypassed. A thorough explanation of these processes is that by Randol\(^3\) (see also section 2.2).

### 2.4 Aerosol Classification

The term aerosol refers to “a dispersion, in a gaseous medium, of solid or liquid particles which have a negligible settling velocity” – World Health Organisation (WHO).\(^6\) The solid particles form “solid particles aerosols” (and not “solid aerosols”), the liquid particles form “liquid particles aerosol” (and not “liquid aerosols”). Particulate pollutants are usually referred to as airborne dispersions of solids that have essentially no vapor phase present (e.g. silica particles, coal dust).

From a practical viewpoint it is impossible to classify an aerosol according to a single criterion. There are several forms of classification based mainly on their physical state, behavior, and action upon living organisms. Some common forms of classification follow.

#### 2.4.1 Physical Classification (Common Terms Used in Describing Aerosols)

- **Dust** is a loose term used for solid particle aerosols. It usually refers to particulates predominantly larger than colloidal dimensions and capable of temporary suspension in air or other gases. Dust is commonly obtained from larger masses through the application of physical force.

- **Fume** refers to solid particles generated by condensation from gaseous state, usually after volatilization from melted substances. Fume formation often implies a chemical reaction such as oxidation. Popular usage includes any type of contaminant.

- **Smoke** refers to particles resulting from incomplete combustion of organic matter and consisting predominantly of carbon and other combustible materials.

- **Mist** is a term applied to liquid particle aerosols composed mainly of particles large enough to be seen by the naked eye.

- **Fog** is a loose term applied to liquid particle aerosols of natural provenance. Formation by condensation is implied.

- **Smog** represents a combination of smoke and fog implying natural and man-made sources.

**Bioaerosols** is a loose term used to describe airborne particles of biological origin. According to American Conference of Governmental Industrial Hygienists (ACGIH)\(^7\) bioaerosols include microorganisms and
fragments, toxins and particulate waste products from all varieties of living things.

The usual types of aerosols encountered in indoor environment include dust, fume, smoke, mist, and bioaerosols.

2.4.2 Classification According to Dimensions and Behavior

Setttable Particulates refers to particles large enough to settle out of the air fairly fast. The term implies particles usually larger than 30 µm, but in still air some particles of 10 µm or smaller may settle. The settled particles are sometimes collected for bulk analysis.

Suspended Particulates refers to aerosol particles that tend to remain suspended in the atmosphere for long periods of time. The term commonly addresses particles of 10 µm and smaller. Alternative names are total suspended particulate (TSP) or suspended particulate matter (SPM).

Condensation Nuclei – sometimes called Aitken nuclei – refers to particle in atmospheric suspension having a diameter smaller than 10⁻¹ µm but greater than 10⁻³ µm. Due to their small dimensions, the Aitken particles do not act as normal condensation sites except as for the important super-saturated vapors in the atmosphere.

Agglomerates refers to particles composed of several smaller particles, attracted to a large particle or to each other, that travel together in the atmosphere as a single particle.

There is no sharp cut-off between particle size in any of these definitions and the dimensions of the particles in each class overlaps its neighboring class. Several factors such as shape (which affects the aerodynamic properties), density and velocity, and electrical charge affect the proper collection and classification of the particles.

2.4.3 Classification According to Industrial Hygiene Conventions and Regulations

Inhalable fraction refers to particles that may deposit anywhere in the RT.

Thoracic fraction refers to particles that, upon inhalation, deposit mainly in the thoracic region of the RT.

Respirable fraction refers to particles that, upon inhalation, deposit mainly in the alveolar region. For complete definitions of inhalable, thoracic and respirable fractions, see also section 7.

PM 10 (Particulate Matter 10) refers to particles equal to or smaller than 10 µm.

PM 2.5 (Particulate Matter 2.5) refers to particles equal to or smaller than 2.5 µm.

Ultrafine particles usually refer to particles having a diameter smaller than 0.1 µm. The toxicological significance of the ultrafine particles is still under research.

Therefore, this term is encountered in the exposure regulatory acts only in few countries. Such an example is The German List of Maximum Allowable Concentrations in Workplaces.

2.4.4 Classification According to Health Effects

Irritants are materials which possess a corrosive or vesicant action. They may affect the human RT but also the eyes and the skin. Typical examples are the acid mists and alkaline dusts. Fibrosis-producing dusts represent solid particle aerosols that cause lung fibrosis (e.g. silica and asbestos). Systemic poisons are those aerosols that may cause organic injury to several tissues or organs (e.g. toxic metals such as lead, mercury, cadmium, etc.). Allergens apply especially to dusts causing allergic reactions (e.g. home dust mites). Carcinogens represent aerosols that contain substances with carcinogenic potential (e.g. nitrosamines, asbestos etc.).

It should be noted that classification according to the health effect does not allow a sharp distinction between various types of aerosols, because it is frequently impossible to place a material in a single class. For example, asbestos may be regarded both as a fibrosis-producing and carcinogen toxin.

3 SOURCES AND TYPES OF AEROSOLS IN INDOOR AIR

3.1 Industrial Environment

The industrial environment is characterized by the presence of various types of fumes, mists, dusts and smoke, according to the type of industry and the technological processes involved.

3.1.1 Metallic Fumes

Metallic fumes are widespread contaminants in industry. Among these, welding fumes are of particular importance since they may be encountered in any industrial environment. According to WHO, welders constitute between 0.5 and 2% of the total working populations with elevated fractions for certain industrial sectors.

The target organs in exposure to welding fumes are the eyes, skin, respiratory system, and the central nervous system. Symptoms include metal fume fever, dyspnea, cough, and muscle pain. Ozdemir pointed out that welders have increased risk of chronic bronchitis and impairment of pulmonary function. Antonini revealed that freshly generated stainless steel welding fumes were more biologically active than the “aged” ones. In 1990 the International Agency for Research on Cancer (IARC) declared welding fumes as possibly carcinogenic
to humans (Group 2B) with lung as the cancer site. In addition, Gustavsson\textsuperscript{(14)} emphasized an association between welding fume exposure and an increased risk of pharyngeal and laryngeal cancer. However, there are studies that do not agree with significant excess of lung cancer, such as that of Danielsen.\textsuperscript{(15)} The complexity and diversity of the biological effect is strongly related to the welding technology.

Roughly, four techniques account for 60–80% of all welding. Manual metal arc welding (MMA) and tungsten inert gas (TIG) are performed with hand-held electrodes with or without an inert gas shielding. The corresponding semi-automatic processes are generically entitled metal active gas (MAG) and metal inert gas (MIG). Other techniques encountered in practice are oxyacetylene (autogen), submerged arc, laser beam and electron-beam welding. The materials commonly welded are mild steel, stainless steel and aluminum. Inert gas techniques produce smaller quantities of fumes. In fumes generated by MMA the relative concentration of the elements may be very different from those in the consumables. Some elements with lower boiling points (F, Mn, Zn, Pb, As, Ca, Si) are significantly enriched in the fume over their sometimes trace concentration in the consumable or the parent metal. For the MMA/mild steel technique, the primary constituents of the fumes are Fe, Mn, Si, Na, Ca, F, while stainless steel welding introduces Cr and Ni as additional compounds. Fumes generated by MIG welding are less complex because of the absence of flux coating. If mild steel is welded, the primary constituents are Fe, Mn, Si and their oxides. If stainless steel is welded, Cr and Ni are also found. The hexavalent chromium content is dependent on the welding technique. MMA/stainless steel fumes contain approximately 3–4% Cr(VI) while MIG/stainless steel fumes contain 14–18%. In the case of the MMA, the crystalline fraction in the fumes may fall in a very wide range, from 20 to 90% of the composition. The predominant crystalline substance is Fe\textsubscript{3}O\textsubscript{4} but X-ray diffraction (XRD) also revealed other compounds such as NaF, CaF\textsubscript{2}, K\textsubscript{2}CO\textsubscript{3}, MgO, K\textsubscript{2}CO\textsubscript{3}, Na\textsubscript{2}CO\textsubscript{3}, MnFe\textsubscript{2}O\textsubscript{4} and KCF\textsubscript{3}.

MIG and MMA produce fumes with a mass median \(d_{\text{sc}}\) in the range of 0.1–0.5 \(\mu\text{m}\) which may deposit predominantly in the lower RT. Larger particles are also generated due to the spray from the arc. Hewett\textsuperscript{(16,17)} emphasized that the particle size distribution and physical properties of the fumes depend more on the welding technique than on the welded material. Inert gas welding techniques generate smaller particles regardless of whether mild or stainless steel is welded.

Due to the above mentioned factors, welding fumes must frequently be tested for individual constituents (see also section 5.2.1). If no toxic elements are present in the welding rod, or in the welded metal or metal coating, conclusions based on total concentration (gravimetric assay) are adequate.

Other branches of industry, such as metallurgy and metal surface treatment shops, are also assessed for potential exposure to metallic as well as nonmetallic fumes. These fumes may contain metallic species already mentioned earlier, but also cobalt fume, Co [CAS 7440-48-4], copper fume, CuO [CAS 1317-38-0], magnesium fume, MgO [CAS 1309-48-4], rhodium fume, Rh [CAS 7440-16-6], vanadium fume, V\textsubscript{2}O\textsubscript{3} [CAS 1314-62-1] and zinc chloride fume, ZnCl\textsubscript{2} [CAS 7646-85-7]. The primary target for the metallic fumes is the respiratory system and the impact may vary from symptoms like ‘fume fever’ and muscle ache to diseases such as occupational asthma. Of a distinctive toxicological significance is the cadmium fume. It contains mostly CdO [CAS 1306-19-0] and is a potent occupational carcinogen (Group 1 in the IARC classification).

The ammonium chloride fume, NH\textsubscript{4}Cl [CAS 12125-02-9] is a widely encountered nonmetallic aerosol, mainly in metallic surface treatment shops. This type of fume is primarily an irritant due to the emission of HCl [CAS 7647-01-0] which takes place in contact with moist surfaces (such as the inner surface of RT).

### 3.1.2 Mists

Mists, particularly acid mist and oil mist, are widely encountered in the industrial environment.

Acid mist is a loose term describing a liquid particle aerosol composed of strong inorganic acids. The acid mists are primarily irritants but in 1992 IARC\textsuperscript{(18)} classified occupational exposure to strong inorganic acid mists containing sulfuric acid as being carcinogenic to humans (Group 1). Further studies such as of Steenland\textsuperscript{(19)} confirmed this classification.

Strong inorganic acids may be encountered in the workplace atmosphere as mist, vapor and gas. The inorganic acids widely encountered as mist are: hydrochloric acid (mostly gaseous but also as mist), nitric acid [CAS 7697-37-2], sulfuric acid [CAS 7664-93-9] and phosphoric acid [CAS 7664-38-2]. Hydrogen bromide [CAS 10035-10-6] is also encountered but to a lesser extent. These acids are usually sampled and analyzed together. For example, the Occupational Safety and Health Administration (OSHA) analytical method ID-165SG quantifies HBr, HNO\textsubscript{3}, H\textsubscript{3}PO\textsubscript{4} and H\textsubscript{2}SO\textsubscript{4} using the ion chromatography (IC) technique. The industries in which there is potential exposure to strong inorganic acids are listed in Table 1.

Another mist of particular toxicological concern is the chromic acid mist. It contains CrO\textsubscript{3} [CAS 1333-82-0] and chromates. Due to the content of chromium compounds, IARC (1990) classified chromic acid mist as human carcinogen (Group 1). Recent studies such as of
Sorahan et al.\textsuperscript{(20)} are consistent with this classification. The exposure to chromic acid mist occurs mainly in the metal plating industry.

The size distribution of acid mists is practically unknown. Routine analytical methods, such as of OSHA method ID-215 for the determination of hexavalent chromium, do not imply size-selective collection of this type of aerosol.

Oil mists are in general referred to aerosols composed of white mineral oil. Alternative names of some water-insoluble petroleum-based cutting oils are sometimes used: cable oil, cutting oil, drawing oil, engine oil, heat-treating oils, hydraulic oils, machine oil and transformer oil. A more detailed definition refers to mist composed of heavy mineral oil [CAS 8012-95-1] having the general formula $C_nH_{2n+2}$ ($n \geq 16$).

Mineral oil mists may be encountered in industries which involve processing of metallic components such as machine-tool construction, ball bearing manufacturing, automotive and aircraft construction, but also in small workshops in which metal cutting is performed. Industries involving the use of heavy machinery (such as turbines or rolling mills) are also potential oil mist environments.

The chemical composition is variable. Fresh oil is supposed to contain only aliphatic hydrocarbons. The burned oils resulting from the lubrication of the mechanisms that operate at high temperatures also contain aromatic hydrocarbons such as PAHs.

The influence upon human health depends strongly on the nature of the oil. In the case of mineral oil [CAS 8012-95-1], the common symptoms are irritation of the eyes, skin, and RT. In the case of mineral oil [CAS 8002-05-9] (Chemical Abstract Name: Petroleum, synonym “Petroleum distillate”) IARC decided that untreated and mildly-treated oils are carcinogenic to humans (Group 1, 1987).

As in the case of the acid mists, not very much is known about the size distribution of the droplets. The routine assays, such as that described in method number 5026 issued by the National Institute of Occupational Safety and Health (USA) (NIOSH), involve collection of the inhalable fraction on filters. However, Kira\textsuperscript{(21)} emphasized the importance of the respirable fraction and suggested that measurements of oil mists have to be size-selective.

### 3.1.3 Dusts

Dusts represent widely spread contaminants in the workplace that may contain metallic or nonmetallic species.

Metallic dusts contain elements that are found also in metallic fumes. Of particular interest are dusts that contain Cr, Cd, and Pb, because of their carcinogenic potential. Lead dust may be encountered also in nonindustrial environments (see also section 3.2).

Silica dust is one of the most studied chemical hazards. Its fibrogenic action has been known for a long time and the occupational exposure is regulated in most countries. Silica has many crystallographic forms but only crystalline forms are known to impose a serious threat to the human health. Two natural forms, $\alpha$, $\beta$-quartz [CAS 14808-60-7] and $\alpha$, $\beta$-cristobalite [CAS 14464-46-1] are classified as being carcinogens to humans (Group 1). An authoritative review of the silica is that by IARC\textsuperscript{(22)}.

The fibrogenic and carcinogenic potential of silica dusts depend on two factors: the crystalline silica content of the dust and the size of particulates. Recent data revealed that the biological response to crystalline silica may differ for samples identical in their bulk analysis and the discrepancies are to be attributed to surface properties such as hydrophilicity, surface radicals or the presence of some surface impurities.

</table>

The main activities in which occupational exposure may occur are listed in Table 2.

Fiber dusts (or simply fibers) refer to aerosols constituted mainly of fibrous materials.

Asbestos [CAS 1332-21-4] is a generic name used for a naturally occurring number of silicates divided in two main groups: the serpentine and the amphiboles. Chrysotile [CAS 12007-29-5], a serpentine, is widely used for the reinforcement of various materials (e.g. cement) due to its high resistance to alkalis and high tensile strength. The amphiboles, anthophyllite [CAS 17068-78-9], amosite [CAS 121172-73-5], actinolite [CAS 121172-67-7], tremolite [CAS 14567-73-8] and crocidolite [CAS 12001-28-4] are also used but to a lesser extent. Asbestos is very persistent in indoor environments. Once released in the atmosphere, it spends a long time before it settles and the depositions may be further re-dispersed due to various indoor activities. Chronic inhalatory exposure to asbestos leads to asbestosis, a historically known lung fibrosis, but the great concern arises from its carcinogenic potential. Asbestos is a potent carcinogen classified by IARC in Group 1. All the crystallographic varieties have been linked to excess of lung cancer and mesotheliomas of the pleura and peritoneum. Advised monographs concerning asbestos problems are that by IARC (Vol. 14, Suppl. 7; 1987) or Sloff and Montizaan.

ors. These devices operate on light scattering principle. 
The identification and quantitation of asbestos in vari-
ous products require the analysis of bulk samples. The 
most frequently encountered techniques are the XRD 
(e.g. method NIOSH 9000), infrared spectroscopy (IR), 
polarized light microscopy (e.g. method NIOSH 9002), 
differential thermogravimetry, light scattering by magnet-
ically orientated fibers and selective staining of asbestos 
fibers.
Asbestos and MMMFs are used as reinforcing agents 
for composite materials and also as insulating materials. 
Therefore, exposure is encountered in a wide variety of 
industries such as construction materials, automotive and 
aircraft industry, metallurgy and chemical industry.
Organic fibers is a generic name for fibers produced 
by chemical synthesis. A review of health data by 
the International Programme on Chemical Safety is 
recommended. The organic fibers extensively used in 
practice are carbon graphite fibers, aramid fibers (e.g. 
Kevlar®) and polyolefin fibers. The aramid fibers are 
produced by reaction of aromatic diamines and aromatic 
diacid chlorides. The polyolefin fibers are synthesized 
by polymerization of different olefin units such as ethylene 
or propylene.
Little is known about their hazardous potential except-
ing the fact that para-aramid fibers may release very 
fine fibrils by peeling of the relatively large fibers. The 
para-aramid fibers were further re-evaluated in 1997 by 
IARC and explicitly classified in Group 3 (unclassifiable as to carcinogenicity to humans). The exposure 
assessment methodology derives from that of asbestos 
and MMMFs. Fibers are collected by air filtration and 
and further evaluated by PCOM. Carbon and aramid fibers 
are used in aerospace, military and other industries for 
the improvement of composite materials. Polyolefin fibers 
are used in textile industry.
Natural fibers such as cotton, wool, and hemp are com-
mon materials used in the textile industry. Natural fibers 
exert their hazard potential mostly upon RT. Symptoms 
include cough and discomfort. Chronic exposure to cotton 
dust leads to bronchitis and a specific disease called byssi-
nosis. Unlike the mineral fibers, the hazardous potential 
arises mainly from the very nature of the fiber rather 
than the size. Consequently, concentration in the air is 
expressed in terms of quantity per a given volume of air 
(e.g. mg m⁻³) and is determined by gravimetric assay.
Of particular importance is the wood dust. Apart from 
its irritative potential, in 1995 IARC classified wood dust 
as being carcinogenic to humans (Group 1). The cancer 
site is the nose sinuses. The hazardous potential seems to 
arise more from the very nature of the particulates and less 
from their dimensions. The hard essence woods are more 
biologically active than the soft ones. The concentration 
in the air is determined by gravimetric assay.
Alkaline dusts is a loose term referring to particulate 
matter containing strong alkalis such as NaOH [CAS 
1310-73-2], KOH [CAS 1310-58-3], LiOH [CAS 1310-65- 
2], and basic salts. Alkaline dusts are basic, hygroscopic, 
caucious aerosols encountered in various branches of chem-
ical industry (petroleum refining, fertilizers and polymer 
syntheses, detergents and cosmetics manufacturing, etc). 
The target organs are the respiratory system, eyes and skin. 
The primary symptom is irritation. Over long time 
exposures pneumonitis and temporary loss of hair may 
develop. The alkaline dusts are sampled as inhalable 
fraction and the alkali content is quantified by titration as 
in method NIOSH 7401.

3.1.4 Tar and Soot

Workplace exposure to tar and soot occurs mainly in the 
coke production and coal based power plants. Coke fur-
naces emit tar through slits around the doors and charging 
holes. IARC (1987) classified coke production as an expo-
sure circumstance carcinogenic to humans (Group 1). As
in many combustion products, the carcinogenic potential arises from the presence of PAHs. For sampling and analysis of PAHs see section 5.2.2.

3.2 Home

Home air contaminants may originate within the building or be drawn in from outdoors. There are hundreds of types and sources of particles present in the home environment depending on the individual habits, tradition, and the general economic development. Home aerosols comprise fumes, mists, dusts, and particles of biological origin.

3.2.1 Fumes and Mists

Fumes and mists are generated by heating and cooking. These processes involve a large number of ingredients, materials and techniques which strongly depend on the lifestyle of the inhabitants. Smith cited by Gold estimated that about one half of the world’s population is exposed to concentrations of PAHs that are orders of magnitude greater than those normally found in areas using more advanced combustion systems. The investigations undertaken in the Chinese province of Xuan Wei, in which nonsmoker women had higher cancer incidence rate due to exposure of fumes originating from smoky coal combustion, revealed a higher PAH airborne burden. Table 3 presents a list of compounds. Chiang and more recently Wu demonstrated that the usage of lard, soybean oil, and peanut oil in Taiwanese kitchens generates fat and oil mist that exhibit mutagenic and genotoxic activity. Chemical analysis of the oily mists revealed extremely high concentrations of dibenz[a,h]anthracene, benz[a]anthracene, and benzo[a]pyrene in the microgram range (for CAS numbers see Table 6). These concentrations are of entirely comparable range with workplace concentrations previously reported for various branches of industry in Western Europe by Montizaan. By contrast, in Western countries aerosols generated by heating and cooking result in much lower concentrations. A thorough discussion of indoor carcinogens is that by Gold.

Environmental tobacco smoke (ETS) is a combination of sidestream smoke released into the air from tobacco burning and mainstream smoke exhaled by the active smoker. ETS is the most widely spread source of indoor pollutants in residences, offices and public places. Tobacco smoke contains several hundreds of toxic compounds both in gaseous form (carbon monoxide, nitrogen dioxide, ammonia, etc.) and particulate-bound form (PAHs, nitrosamines, cadmium, etc.). The size of the aerosol is in the respirable range (usually between 0.2 and 0.5 µm) and varies due to the evaporation or coagulation of the individual components. The composition is also variable according to the tobacco brand and the smoking habit (e.g. cigarette or pipe). The marker compounds used for ETS evaluation are: particulates (assessed both as TSP or respirable fraction), nicotine, carbon monoxide and nitrogen oxides. Lebret et al. cited by Gold suggested cadmium as a possible marker.

Acute effects of exposure to indoor combustion fumes (heating, cooking, ETS) are irritation of RT and eyes, coughing, wheezing, headache and related sinus problems. The carcinogenic potential arises from the content in chemicals such as benzene [CAS 71-43-2], PAHs, and nitrosamines.

3.2.2 Dust

Dust is commonly referred to particles of various origin present in indoor environments. Apart from being annoying, the home dust may impose a serious threat

* Below detection limit.

to the human health, depending on the contained compounds. Some common toxins present in the home dust are fibers, lead, pesticides, and particles of biological origin.

Fibers may be either natural (hair, wool, cotton, etc.) or MMMFs. Asbestos, if present in home environment, represents a source of concern. The main sources are the insulation products and building materials (e.g., floor tiles, dry wall compounds, reinforced plaster, insulation of pipes, etc.), the use of diverse home appliances (hair dryers, air treatment devices) and the outdoor air. High concentrations of asbestos develop indoor during maintenance operations. Extensively used in the past, asbestos is now severely limited in many countries.

The main sources of lead are paints, pipes and outdoor particulates. Lead paints may impose a risk when the painted surfaces are not properly maintained. During renovation, sanding and scraping of the surfaces may release large amounts of lead dust. Outdoor SPM, especially in the vicinity of heavy traffic areas, contain significant amounts of lead. The quantities are much lower in countries where lead-free gasoline is used. Contaminated soil is carried in from outside on occupant’s clothes and shoes and may accumulate in carpets. Re-suspension may subsequently develop elevated concentrations in air. Inorganic lead and compounds are possibly carcinogenic to humans (IARC 1987, group 2B).

Pesticides, such as insecticides, rodenticides, termicides, germicides, fungicides, and herbicides, are widely used in residences or in close proximity. Powder conditioned pesticides (especially termicides) and spraying application may lead to airborne concentrations in the microgram range. The threat imposed by indoor pesticides remain somewhat controversial. Lemus et al. detected concentrations up to 2.13 µm of chlorpyrifos but could not emphasize clear acute or long time effects. More recently, Davis et al. declared that spraying of chlorpyrifos constituted a great risk for the children, due to accumulation on toys or other surfaces currently touched by children.

Particles of biological origin include bacteria, viruses, fungi, algae, house dust mite particles, dander, and pollen grains. The generic term is bioaerosols. Bioaerosols arise both from outdoor and indoor sources. Indoor sources include air handling system condensate, water damaged materials, high humidity indoor areas, damp organic material and porous wet surfaces, humidifiers, hot water systems, plants, animals and insects, food, and food products. Indoor levels of bacteria, fungi, and viruses may rise to higher values than outdoors, depending on the ventilation system and degree of activity. Acute health effects include allergic reactions (hypersensitivity pneumonitis, humidifier fever, allergic rhinitis, etc.) and infections (such as legionellosis).

3.3 Nonindustrial Workplaces

Sick building syndrome (SBS) is a general term defining a condition associated with complaints of discomfort (headache, nausea, dizziness, eye, nose, throat, and respiratory irritation, etc.). The specific causes are often not known but sometimes are attributed to the conjugated effects of indoor pollution and individual susceptibility. The symptoms associated with periods of occupancy often disappear after the worker leaves the building. By contrast, the term “building related illness” (BRI) refers to symptoms of diagnosable illness that can be attributed directly to airborne building contaminants. The causes of SBS and BRI are inadequate ventilation and contamination with chemical compounds and bioaerosols from indoor and outdoor sources.

Traditionally, indoor air in health care facilities was investigated mainly for the presence of pathogen agents. However, especially in the pharmacy areas of the hospitals, aerosols containing hazardous drugs are frequently encountered. Antineoplastic drugs, such as vincristine, dacarbazine, mitomycin, cytosine or arabinoside, impose a serious threat during the preparation of injectable solutions or disposal of the equipment. Exposure to methyl methacrylate, an acrylic cement-like substance used in prosthetics, may occur during preparation and mixing. Aerosol treatment sessions are another exposure circumstance. Drugs administrated as aerosols (such as ribavirin) form liquid particle aerosols of about 1 µm that may be also inhaled by the person who conducts treatment and not only by the patient. The substances mentioned above impose a serious threat due to their acute and chronic effects. Most of them exhibit carcinogenic potential. Dental care facilities represent occupational environments in which chemical aerosols may be generated. Harrel revealed that dentistry equipment, such as ultrasonic scalers, generate aerosols and splatter regardless of the type, the power level or the insert. Barnes showed that these aerosols may contain also blood droplets.

3.4 Transportation

Not much is known about composition and size distribution of aerosols in transportation. In aviation, attention was traditionally paid to flight deck crew, cabin crew, and ground support personnel, and less to cabin air quality. However, Dechow measured the concentrations of several contaminants in the passenger cabin and reported that particulate matter contained tobacco smoke and bacteria. The particulates size was identified in respirable range but the air purification systems maintain low levels.

Svendsen investigated marine engineers that are potentially exposed to aerosols arising from engine
functioning. They reported concentrations of oil mists in range of 0.12 to 0.74 mg m\(^{-3}\).

### 4 FACTORS INFLUENCING SAMPLING, STORAGE AND ANALYSIS OF AEROSOLS

It is well documented that the quality of the sample submitted to analysis is crucial in obtaining a reliable result. No laboratory analysis, regardless of the quality of the equipment or the skills of the analyst, can overcome the defects of sampling and storage. The determinants that influence the sampling and storage of the aerosols may be roughly divided in factors pertaining to the very nature of the aerosol (intrinsic) and factors related to the sampling strategy.

#### 4.1 Intrinsic Factors

**4.1.1 The Momentum of a Particle**

Momentum of a particle is the product of its mass and its velocity. The particulates are much larger than the molecules of the gas in which they are dispersed. If the flow direction of the gas changes, larger particles tend to continue their original trajectory. Consequently, larger particles are dispersed to the periphery of the stream and may deposit, thus affecting the original distribution and concentration. The situation is encountered in stack gases and ventilation ducts or if a large object is placed in the main stream. In order to obtain a representative sample, all parts of a gas stream must be sampled.

A greater speed of a gas stream implies a greater momentum for the particles which tend to be lost from the surface of the sampler. Consequently, when collecting a sample this is to be done in such conditions that there is no change in the momentum. The condition is referred to as isokinetic sampling and is accomplished by means of a thin-walled probe aligned with the stream flow and drawing sample at the same (linear) velocity as of the stream flow at that point. Even so, a theoretically 100% efficiency of the sampling is not possible because the probe always has a finite wall thickness that disturbs the flow. Laminar flow of the gas stream will allow truly isokinetic sampling whereas turbulent flow will impede the collection of the larger particles. The collection efficiency may also be affected by the deposition of particles on the walls of the probe. Sample velocity of the air and alignment of the probe are both important conditions of the isokinetic sampling. Fortunately, isokinetic sampling is not necessary for all the applications. Sampling in calm ambient air is not influenced by velocity because slow moving particles have a negligible momentum. Also, particles under about 3µm do not require isokinetic sampling because their small mass minimizes inertial effects.

**4.1.2 Gravitational Effects**

Gravitational effects impose a small effect upon sampling in the case of relatively quiescent air masses such as indoor environment. A thorough discussion about the influence of both the momentum and the gravitational effect may be found in Katz.\(^{37}\)

**4.1.3 Size**

Size influences the sampling of both solid particle and liquid particle aerosols. A larger size implies a greater momentum. In the case of oil mist, Wilsey\(^{38}\) found that the amount of aerosol collected by means of an Institute of Occupational Medicine (IOM) sampler was greater than that collected with an open face sampler.

**4.1.4 Evaporation and Sublimation**

Evaporation and sublimation of aerosol samples during storage is a common phenomenon. Particulate samples are less affected because solids generally have low vapor pressure and the evaporative loss is small. By contrast, liquid samples are susceptible to evaporation even during sampling. Leith\(^{39}\) revealed a significant loss of sample in the case of filter collection when compared with electrostatic precipitation sampling of mineral oil mist. Although the mineral oil used as a machining fluid is not normally considered volatile, when dispersed as mist its surface becomes high. The mist droplets deposited on the surface of the filter are in permanent contact with the air passing through the filter and evaporation takes place. In the case of electrostatic precipitators, droplets are separated from the air flow and coalesce on the precipitator wall to form a film with smaller surface. Differences were emphasized even between different types of filters. Mixed cellulose esters (MCE) retain more oil mist than polyvinyl chloride (PVC) filters.

**4.1.5 Electrostatic Charge**

Electrostatic charge may contribute to sampling errors. Particles may be lost by electrostatic attraction to various components of the sampler. This is of particular importance in asbestos collection. In area sampling, the conductive cowl of the sampler is connected to the ground (e.g. cold water pipe) in order to eliminate the electrostatic charge.
4.2 Factors Related to Sampling Strategy

4.2.1 Location

Inside large industrial buildings the aerosol concentrations may vary by several orders of magnitude within a relatively short radius. Obstacles (such as machinery or elements of infrastructure) interposed into the air stream cause deposition. If the source is small, as in manual welding, high concentration of contaminants are encountered only in the proximate vicinity. The variations of concentration impose that exposure assessments must be achieved using exclusively data based on personal sampling. Area sampling is used only in general surveys of the workplace.

4.2.2 Temperature

Temperature influences the mass and number of the particles. If the temperature is too high, liquid aerosols may vaporize, and if it is too low, water or other vapors may form mists. Also, at the point of emission, some substances may have a fraction in the gaseous phase which in standard collection conditions (21 °C and 700 torr) may turn into liquid or solid particles. This potential fraction is called condensible particulate matter.

4.2.3 Humidity

In environments with high relative humidity (RH), both particulates and the filters used in their collection may absorb water vapors. Liquid particulates (such as of acid mists) may become larger due to absorption. Water absorption is somehow negligible up to about 50% RH but may increase considerably in environments where the steam is used.

4.2.4 Sampling Rate

Sampling rate influences the collection efficiency of filters. A higher sampling rate means a higher air velocity at the surface of the filter. Also, the size-selective sampling devices (e.g. cyclones and cascade impactors) require a certain flow rate in order to operate properly.

4.2.5 Time Interval

The time interval for a proper collection results from the total volume of air which must be drawn and the flow rate used for collection. However, if the concentration of airborne particles is too low, and the total amount of collected material falls under the detection limit of the method, the duration of sampling must be increased. The increase of the flow rate is not recommended because it affects the collection efficiency.

5 INDUSTRIAL HYGIENE APPLICATIONS

There are two main objectives for the aerosol sampling and analyses in industrial indoor environments: the workplace air quality characterization and the personal exposure assessment. In both cases, the accuracy of the evaluation requires a thorough approach to the type of aerosol, the sampling strategy and the method of analysis. Since the situations encountered in practice differ very much it is the analyst’s choice what methodology to apply. Some guidelines and examples follow.

5.1 Sampling Methodology

There are several criteria used in the classification of sampling methodology: the time duration, the size of the particles and the location of the sampling.

According to the time duration, the sampling methods may be classified as:

1. full-period, continuous single sampling; refers to sampling over the entire sampling period with only one sample (e.g. a full-shift sample). This is the preferred method for the collection of aerosols.
2. full-period, consecutive sampling; refers to sampling using consecutive samples of smaller time duration which combined equal the total duration of the sample period. This method is used in case that continuous single sampling leads to filter overloading due to high concentrations of SPM.
3. Grab sampling is defined as the collection of several short-term samples that combined provide an estimate of exposure over the entire period of observation. Grab sampling is applied in aerosol sampling for the assessment of high concentrations that arise during some technological operations with short duration.

According to the size of the particles, the sampling methods are:

1. Sampling for the collection of the entire amount of airborne SPM burden. This operation is encountered in the collection of aerosols for which it is assumed that the hazard potential is not dependent on a certain dimension of the particles.
2. Size-selective sampling implies the collection of particles according to certain dimensional intervals. The sampling uses devices such as stage impactors that are capable of collecting particles of certain dimensions onto separate collection media. Of particular importance is the so-called respirable fraction (see also sections 2 and 7). Substances such as silica have
the hazard potential associated with this mass fraction. The standard device for the respirable fraction collection is the cyclone.

As a function as the location the sampling may be:

1. Area sampling (static) that implies the collection of SPM in a certain fixed location.
2. Personal sampling which means that the samples are collected in the breathing zone of the worker (e.g., within a radius of 30 cm from the nose). This sampling procedure aims to identify the concentrations of the compounds as close as possible to those present in the air that enters RT. The sampler is attached to the worker’s collar and connected to a battery operated pump. The sampling is not performed in a particular area but follows the worker’s motion.

Depending on the objective of the investigation, the sampling strategy combines two or more sampling methods. For instance, in area sampling either the entire amount of SPM or certain fractions of interest, such as PM 10, PM 2.5, and respirable fraction, may be collected. Also, personal sampling may be conducted for the assessment of the inhalable fraction or the respirable fraction. In either case, sampling may be continuous sampling, consecutive sampling, or grab sampling.

5.2 Identification and Quantitation of Workplace Pollutants

The nature of workplace contaminants is generally predictable because they originate from a well-defined and controlled technological process. However, the concentration of individual compounds vary according to the nature and location of the operations. The SPM burden in large industrial buildings comprise substances generated in different workplaces. Therefore, the first step in establishing the background profile is to screen for the expected contaminants in order to gain data regarding their presence and individual concentrations. Screening may involve the evaluation of the number and size distribution of SPM, the quantity of SPM and the presence of the individual compounds. These goals imply the usage of portable monitors, gravimetric sampling and chemical analysis.

The assessment of individual contaminants in the screening procedure requires methods of analysis capable of identifying a number of compounds simultaneously. These methods may also quantify some compounds with reliable accuracy. In the case of other compounds, screening methods give only qualitative information. Therefore, identification is followed by further sampling and quantitation using specific methods.

5.2.1 Screening and Quantification of Metals in Fumes and Dusts

The evaluation of metallic species in fumes and dusts is a typical example of simultaneous analysis. It implies gravimetric assay and chemical analysis. Characterization of different size fractions may be sometimes required. Metals that can be determined by simultaneous or specific analysis are: silver (Ag) [CAS 7440-22-4], aluminum (Al) [CAS 7429-90-5], arsenic (As) [CAS 7440-38-2], beryllium (Be) [CAS 7440-41-7], calcium (Ca), cadmium (Cd) [CAS 7440-43-9], cobalt (Co) [CAS 7440-48-4], chromium (II) (Cr) [CAS 22541-79-3], chromium (III) (Cr) [CAS 16065-83-1], chromium (VI) (Cr) [CAS 18540-29-9], copper (Cu) [CAS 7440-50-8], iron (Fe) [CAS 1309-37-1], lithium (Li), magnesium (Mg) [CAS 1309-48-4], manganese (Mn) [CAS 7439-96-5], molybdenum (Mo) [CAS 7439-98-7], nickel (Ni) [CAS 7440-02-0], lead (Pb) [CAS 7439-92-1], platinum (Pt) [CAS 7440-06-4], selenium (Se) [CAS 7782-49-2], tellurium (Te) [CAS 13494-80-9], titanium (Ti) [CAS 7440-32-6], thallium (Tl) [CAS 7440-28-0], vanadium (V) [CAS 7440-62-2], yttrium (Y), zinc (Zn) [CAS 1314-13-2] and zirconium (Zr) [CAS 7440-67-7].

The content of metals in dusts and fumes is commonly assessed by means of inductively coupled argon plasma atomic emission spectroscopy (ICP AES), flame atomic absorption spectroscopy (FAAS), and graphite furnace atomic absorption spectroscopy (GFAAS). Table 4 presents a summary of three routine methods used in industrial hygiene.

Sampling is performed by collecting the inhalable fraction of dusts and fumes onto MCE filters. Area sampling and personal sampling may be used. In welding fume sampling for individual assessment, the sampler is placed inside the helmet of the welder. Sample preparation involves hot plate acid digestion. However, this procedure does not destroy all matrices. Microwave digestion is a powerful alternative that uses acid treatment at elevated temperature and pressure.

Detection is performed for each element using specific wavelengths. ICP AES based procedure offers simultaneous analysis of all elements but FAAS technique requires changing the lamp for each metallic specie. In addition, FAAS requires a typical 1–2 ml of the final solution for each element. Diluting the solution in order to screen for more elements may result in falling above the detection limit. These limitations of FAAS affects the versatility of the procedure when used for screening purposes. However, if ICP AES equipment is not available, FAAS represents an alternative because it has detection limits suitable for industrial hygiene applications.

Some elements require specific analysis methods. Table 5 presents a list of routine specific methods for different metallic species. These procedures use either

VIS, visible spectrophotometry.

enhanced sample procedure steps or different analytical techniques.

There are some alternative methods available. Hexavalent chromium may be analyzed with NIOSH 7604 method based on IC conductivity detection; cations of metals interfering with the colorimetric method, do not interfere with this method.

NIOSH 7082 is a laboratory method based on FAAS technique for the identification of lead and lead compounds. It has a higher working range than NIOSH 7105 but lower detection limit. Lead sulfide, a compound with particular toxicological interest, is evaluated in the respirable fraction (NIOSH 7505) using XRD.

In field conditions, lead may be detected using chemical spot test (rhodizonate-based)-NIOSH 7700. This is a qualitative colorimetric method for identification of lead in the particulates sampled on filters. On-site filter analysis may be performed by means of portable anodic stripping voltammetry (e.g. method NIOSH 7701) but samples must be first ultrasonicated in HNO<sub>3</sub>. Method NIOSH 7702 avoids sample preparation in field conditions because it uses portable instruments based on X-ray fluorescence (XRF), L-shell excitation technique (cadmium-109 source).

Arsenic compounds may be analyzed by GFAAS. The method NIOSH 7901 is a procedure for the determination of As<sub>2</sub>O<sub>3</sub> [CAS 1327-53-3] and NIOSH 6001 for the analysis of AsH<sub>3</sub> [CAS 7784-42-1].

5.2.2 Sampling and Analysis of Polycyclic Aromatic Hydrocarbons

In practice, the PAH mixtures are too complex and not all individual compounds may be assessed. Therefore, PAHs are evaluated (a) as a total amount of compounds (i.e. not distinguishing between the individual compounds) and (b) using the quantitation of a number of compounds
selected as markers of the presence of PAHs in the mixture.

Some problems are usually encountered in PAH analysis. One drawback is the complexity of the incorporating matrices. The presence of interfering substances that have physical and chemical behavior similar to that of PAHs require complex sample preparation by repeated extraction and purification steps. On the other hand, PAHs are present as complex mixtures containing isomeric structures and derivatives that vary greatly in relative concentration of the individual compounds. Therefore, the analysis focuses only on certain markers.

The analysis of PAHs requires the use of methods with high resolution, response selectivity and constancy, and acceptable cost/performance ratios. It is often impossible to achieve some of the goals simultaneously and the analyst should apply the technique that offers the best result in the given application.

Sampling of PAHs usually requires the collection of large amounts of SPM. The smaller the amount collected, the greater the sensitivity required in identification. Particle-bound PAHs are collected onto glass fiber filters. For the collection of both gaseous and particle-bound PAHs the sampling train comprises filter plus sorbent tube.

Sample preparation implies extraction with solvents such as cyclohexane, acetone, benzene, toluene, and methylene chloride. Furton et al. underlined that supercritical fluid extraction (SFE) is a powerful alternative to conventional liquid extraction. SFE uses mainly carbon dioxide which is a nonpolar compound and limits the recovery of higher molecular PAHs. The extracts may be further cleaned up by adsorption and elution on silica gel, Florisol or alumina columns or by means of solid phase extraction (SPE). SPE uses cartridges filled with various materials (e.g. octadecylsilane C18 – ammonia (NH2), silica–cyano) and require much smaller amounts of solvents than purification on columns.

Separation and detection: Reversed-phase high-performance liquid chromatography (RPHPLC) using octadecylsilane (C18) columns is one of the most popular methods for the separation of PAHs. However, not all C18 stationary phases provide the selective separation for all PAHs. A quantitative measure of phase selectivity is given by the selectivity factor in Equation (1):

$$\alpha_{\text{TBN/BaP}} = \frac{k_{\text{TBN}}}{k_{\text{BaP}}}$$

The $k_{\text{TBN}}$ represents the retention factor of 1,2:3,4: 5,6:7,8-tetrabenzonaphthalene (alternate name dibenzog[p]chrysene) and $k_{\text{BaP}}$ the retention factor of benzo[a]pyrene. The selectivity factor $\alpha_{\text{TBN/BaP}}$ correlates with the retention behavior of PAHs and the type of the bonded phase. A value of $\alpha_{\text{TBN/BaP}} \leq 1$ indicates polymeric C18 phases while $\alpha_{\text{TBN/BaP}} \geq 1.7$ indicates monomeric C18 phases. For values of 1 < $\alpha_{\text{TBN/BaP}}$ < 1.7 the bonded phase synthesis is somehow less certain and may indicate a densely loaded monomeric phase or light polymerization with di- or trifunctional reagents (Wise et al.41). The separation of EPA 16 priority pollutant PAHs can be properly achieved only with columns which have $\alpha_{\text{TBN/BaP}}$ between ca. 0.6 and 0.9. Widely used columns are Supelcosil LC-PAH, Vydac 201 TP, Spherisorb PAH, Erbasil C18 H.

Detection of PAHs is commonly based on ultraviolet (UV) absorbance measurements. The usage of diode-array detectors allow the generation of UV spectra. Further comparison with library spectra leads to enhanced identification. Another common procedure is to use a fluorescence detector in tandem with the UV detector. The identification relies on the fact that many PAHs are good fluorophores. However, some compounds such as acenaphthylene, benzo[ghi]perylen, and indeno[1,2,3-cd]pyrene exhibit low or no fluorescence.

The 254 nm wavelength is used for simple UV scan. For the enhanced identification of a particular compound there are three alternative wavelengths:

(a) 236 nm for fluoranthene, and pyrene;
(b) 254 nm for naphthalene, phenanthrene, anthracene, benzo[a]anthracene, and chrysene;
(c) 299 nm for benzo[b]fluoranthene, benzo[k]fluoranthene, benzo[a]pyrene, dibenz[a,h]anthracene, benzo[ghi]perylen, and indeno[1,2,3-cd]pyrene.

The general analytical steps presented above vary according to the application’s requirements. Four routine methods OSHA 58, NIOSH 5506, NIOSH 5800 and Method 102A & D will be briefly presented as an example. Table 6 presents the list of compounds that may be identified by means of these methods.

NIOSH 5506 is a method directed towards personal sampling. It allows sampling of both gaseous and particle-bound PAHs. The absence of a cleanup step reduces the loss of PAHs but may impose a negative influence upon chromatographic separation. The characteristic peak of a compound may overlap the peak of the neighboring compound. A thorough adjustment of the solvent gradient may be necessary for good separation. The application area includes evaluation of fumes generated in the aluminum industry, coal liquefaction plants, coal gasification plants, creosote treatment facilities, graphite electrode manufacturing, and also the analysis of asphalt fume, coal tar pitch and coke oven emissions, diesel exhaust, petroleum pitch, and fumes that are generated during roofing.

* The solvent choice is based on comparative trials.

NIOSH 5800 is not based on high-performance liquid chromatography (HPLC); it uses flow injection into a fluorescence detector and identifies the total polycyclic aromatic compounds (PACs) fraction in aerosols (defined as all compounds producing detectable fluorescence at the chosen wavelengths). This method is used for the comparison of environments using the same fume source. The total PACs burden is assessed by comparison with standard solutions of PACs. Therefore, only PACs present in the standards will be identified.

OSHA 58 represent in fact two methods in one: (a) the quantitation of total PAHs by gravimetric assay of the benzene extractable fraction, and (b) the identification of some individual compounds. The gravimetric measurement is very useful since regulation of PAHs in many countries rely on it. The identification of individual compounds is somehow limited. Also, the method is limited to the particle-bound PAHs.

Method 102A & D is tedious but very flexible. It may be used for area sampling, personal sampling and size selective sampling. The extraction solvent (cyclohexane) is selective for nonsubstituted PAHs but Soxhlet extraction assumes long periods (a minimum 8 hours is required). Cleanup on silicagel is versatile and ensures better conditions for the separation and identification even when simple UV detection is involved. However, this step may induce sample loss and is time-consuming. This method is suitable for both industrial and
nonindustrial applications and is dedicated to particle-bound PAHs.

Table 7 presents a summary of these four methods. HPLC has limitations in terms of detection limits. Increasing the sampled volume might not represent always the best solution (see section 8). Consequently, more sensitive techniques are sometimes required. A common alternative is gas chromatography/mass spectrometry (GC/MS). The use of capillary columns provides good separation for PAHs and the mass spectrometry detectors are suitable for identification of compounds in mixtures. Another alternative is to upgrade the HPLC analysis by using it in conjunction with a more powerful method of identification such as Shpol’skii spectroscopy (SS). SS is especially suited for the qualitative analysis of PAHs at trace levels. An industrial hygiene application is reported by Ariese.

5.3 Assessment of Human Exposure

The assessment of human exposure to aerosols implies measurements of the airborne concentrations of those toxins to which a person comes into direct contact during a certain time interval. The measurements rely exclusively on personal sampling. The samples are collected as inhalable dust or as respirable fraction according to the toxicological behavior of the compound that will be analyzed.

The assessment of human exposure to silica dust requires the identification and quantitation of the crystalline silica in the respirable fraction (see also section 3.1). Routine analyses rely on three techniques: XRD, IR and VIS. Some common methods are: NIOSH 7500, NIOSH 7501, NIOSH 7601, NIOSH 7602, NIOSH 7603, and OSHA ID-142. A brief characterization is presented in Table 8.

5.3.1 Sampling

Sampling implies personal sampling using cyclones. The flow rate is adjusted in order to achieve a median cut-off point of 4 µm (see also section 7). The samples are collected on filters that must be weighted before and after the sampling. Sample weights of 0.5 to 3.0 mg are preferred. Some substances such as aluminum phosphate, feldspars, graphite, iron carbide, lead sulfate, micas, montmorillonite, silver chloride, and talc may interfere during the analysis. Therefore, the field operations must include the acquisition of information regarding the possible presence of interfering substances and also bulk samples.

Sample preparation is specific to the analytical method. General procedures for XRD and IR techniques involve the destruction of the filter used in collection by one of the following techniques: muffle furnace, low-temperature (radio-frequency) plasma ashing or filter dissolution in organic solvents (e.g. PVC filters in tetrahydrofuran). Additional steps of ultrasonication or acid treatment are included in order to break up the agglomerates and to overcome the influence of interfering substances. For XRD analysis, the recovered material is deposited onto a silver membrane filter. In case of the IR analysis, the ashen material is usually incorporated into KBr pellets, as in method NIOSH 7602. An alternative is that of scanning directly on thin layer deposits (method NIOSH 7603). In this case, the ashed material is suspended in 2-propanol and then redeposited by filtration on a 47-mm diameter, 0.45-µm pore size, vinyl chloride–acrylonitrile copolymer membrane filter.

The VIS technique involves hot plate acid digestion of the collected filters. The noncrystalline fraction is then treated with concentrated H3PO4 (85%) and the phosphates are dissolved in water and filtered. The crystalline silica deposited on filters is treated with H2PO4 (85%) and the acid excess is neutralized with boric acid solution. The first step in the color development is the treatment with molybdate reagent prepared from ammonium molybdate tetrahydrate [CAS 12054-85-2], in deionized water and concentrated sulfuric acid. The silicomolybdate complex is yellowish. If color does not develop, a second treatment with 1-amino-2-naphthol-4-sulfonic acid is performed in order to obtain the molybdenum blue complex (blue color). The silicomolybdate complex will cover a range of 0.1 to 2.5 mg of SiO2 and the molybdenum blue complex a range of 0.02 to 0.15 mg of SiO2 in the sample.

5.3.2 Analysis

Equation 2 gives the Bragg relation on which the X-ray technique is based:

\[ n\lambda = 2d \sin \theta \]  

in which:

- \( n \) = order of diffracted beam
- \( \lambda \) = wavelength of X-ray beam (in angstroms)
- \( d \) = distance between diffracting planes (in angstroms)
- \( \theta \) = angle between incident X-rays and the diffracting planes (in degrees); \( 2\theta \) for most spectrometers

Quartz, cristobalite and tridimite can be identified and quantified on three or more different angles of diffraction. Informational values are listed in Table 9. Values correspond to \( 2\theta \) degrees and should be regarded rather as informative than absolute since peak locations depend also on the instrument.

In IR, scanning is performed usually from 1000 cm\(^{-1}\) to 600 cm\(^{-1}\). The peak of interest for quartz is located at 800 cm\(^{-1}\). If the samples were ashed at low temperature and kaolinite is present, a correction must be applied. Five different concentrations of purely kaolinite samples are scanned at 800 cm\(^{-1}\) and at 915 cm\(^{-1}\) (the maximum absorption bands for kaolinite). Then a curve is prepared and used for correction of the absorbance value at 800 cm\(^{-1}\).

VIS involves a classic color measurement. The silico-molybdate is measured at 420 nm. The molybdenum blue complex is measured at 820 nm.

The methods based on XRD and IR are highly specific and require relatively simple sample preparation. The VIS method is rather tedious but offers a fairly good precision and require lower skilled personnel. A comparison between the performances of these techniques applied in different laboratories over a long period of time may be found in Shulman.\(^{44}\)

As stated earlier in this article, surface analysis is required for complete investigation of toxicological properties of silica. Low-voltage scanning electron microscopy may be employed for the detection of clay occlusion of quartz particles. The surface composition may be determined by laser microprobe mass analysis. This technique uses a laser beam to vaporize a small volume of material from the surface of a single quartz particle and the ions generated are identified with a time-of-flight mass spectrometer. Detailed surface analysis may be also performed by means of scanning electron microscopy with energy dispersion X-ray analysis or X-ray photoelectron spectroscopy.

6 NONINDUSTRIAL APPLICATIONS

6.1 Objectives and Procedures

Common objectives for the analysis of indoor SPM are the investigation of the IAQ profile, the investigation of the sources, and the assessment of exposure. Wilson\(^{45}\) emphasized that the comparison with outdoor concentration (the calculation of the indoor/outdoor SPM ratio) is a relevant parameter for epidemiological studies. It may indicate the prevalent source of a particular contaminant. The operations involved in the assessment of indoor SPM comprise chemical and biological analysis, counting, and sizing.

The measurements of indoor SPM are conducted as to assess the average concentrations as well as the maximum concentrations. Some directions for maximum concentration measurements are:

1. ventilation must be diminished to facilitate accumulation (e.g. doors and windows shut or air conditioning systems kept to a minimum recirculation rate);
2. the samples must be taken at 1–2 m height in the area closest to suspected source and during the maximum source activity;
3. the occupants must carry out full normal activity including those that are supposed to create resuspension of the settled particulate matter;
4. samples must be taken both in winter and in summer;
5. the duration of sampling depends mostly on activity of the source of SPM contamination; direct instruments must be used if the emissions are short timed so that the sampling would not provide enough material for the analysis;
6. the number of samples is roughly double in air conditioning environments compared to natural ventilated buildings.

An analysis of sampling strategies for indoor sampling is given by van de Wiel.\(^{46}\)

The SPM is collected on filters. The investigation often require the usage of size-selective sampling devices. Chemical analysis employs techniques usually derived from industrial applications.

Heating, ventilation and air conditioning (HVAC) systems that are used in many buildings, both in office and residential environments, are subjected to verifications during IAQ assessment. One characteristic of interest for these devices is the filtration efficiency, which represents their ability to clean the air by retaining the airborne SPM. The size and number of particles are determined before and after passing the HVAC. Then the filtration efficiency is expressed as the percent of particles of a certain size fraction captured by the filtration system (e.g. HVAC retains particles of ≤1 μm with 98% filtration efficiency). Counting and sizing for the investigation of HVACs is performed by direct reading instruments based usually on light scattering. The laser diffraction particle counters represent an alternative because of their enhanced precision and lower detection limits. Detection limit refers to the smallest particle that can be detected and counted.

In the case of ventilation duct measurements (e.g. inlets for fresh air supply) the sensors are equipped with isokinetic probes (see also section 4). It is also advisable to use dual particle counters in order to minimize the errors that occur in field particle counting.

Detailed investigations of HVAC systems may include biological contamination because humidifiers are often a source of microorganisms.

6.2 Analysis of Bioaerosols

Indoor biological pollutants often constitute a cause of concern in the indoor nonindustrial environment. The assessment of bioaerosols is a complex operation which requires knowledge of many specialists as industrial hygienists, biologists, chemists, medical professionals, epidemiologists, statisticians, ventilation engineers, etc.

Sampling of aerosols includes almost every principle applied for separating particles from air, from sedimentation, filtration, impingement to electrical and thermal precipitation. Use of open plates of solid nutrient media is inefficient. Cascade impactors and all-glass impingers proved to have collection efficiency good enough to be considered as standard sampling instruments. The collection efficiency of a bioaerosol sampler refers to: (a) the physical collection efficiency, which implies the capacity of the sampler to separate the biological particles from the air; and (b) the biological collection efficiency, which implies the capacity of the sampler to preserve the integrity and biological activity of the microorganisms during sampling.

A general procedure for sampling culturable microorganisms such as bacteria, fungi, and thermophilic actinomycetes is the method NIOSH 0800. The sampling involves drawing the air through an Andersen cascade impactor fitted with culture media plates. Culture media include agar derivatives such as malt extract agar and trypticase soy agar, but other media may be used according to the microorganisms intended for identification.

Once the particles have been collected they can be analyzed by one of the following techniques:

1. Culturing of viable cells is one of the most frequently used methods. The samples are inoculated onto any type of culture media and incubated under whatever conditions of temperature, humidity, and lighting as are necessary to grow the collected microorganisms. The microorganisms are then identified by their distinctive individual colonies. The culture of sample isolates is suitable for the identification of infectious agents as Legionella, the measles virus (rubeola), etc.

2. Direct examination of particles is useful in identification of allergic agents as pollen grains and spores of the fungi. The samples are stained and then examined under a microscope. The staining methods include either direct use of Gram stain or the immunoassay technique using fluorescent antibodies. In the latter case, a specific antibody that is conjugated with a fluorescent dye combines with the microbial agent located onto the surface of the cell forming a complex. The fluorescent complex may be observed by means of a fluorescent microscope.

3. Instrumental analysis employs the use of an analytical technique such as chromatography. NIOSH 0801 method provides a procedure for the identification of airborne bacteria by means of gas chromatography/flame ionization detector (GC/FID). The samples are cultured onto nutrient media and then harvested. The fatty acids C9 – C20 are first separated from the harvested material by saponification and further methylated to obtain fatty acid methyl esters (FAME). The material is subjected to GC/FID analysis in order to obtain a FAME profile characteristic to each bacteria. Identification is based on comparison with a profile library of FAME.

In the field, identification of biological particulates may be performed by means of direct reading instruments. These portable devices use the fluorescent properties exhibited by biological particulates when exposed to UV radiation.

7 REGULATIONS AND AIR STANDARDS

In the working environment, the control of airborne toxins relies on the use of the threshold limit values (TLVs). TLVs are numbers that refer to airborne concentrations of substances and represent conditions...
under which it is believed that workers may be repeatedly exposed without adverse health effects. However, due to variations in individual susceptibility, some workers may experience discomfort or even serious disturbance at concentrations at or below TLV. Therefore, TLVs do not represent perfectly safe limits but only recommendations and guidance for practice. There are three ways of expressing TLVs:

1. Threshold limit value/time weighted average (TLV/ TWA, or simply TWA); ACGIH\(^7\) defines TWA as being "the time-weighted average concentration for a conventional 8-hour workday and a 40-hour workweek, to which it is believed that nearly all workers may be repeatedly exposed, day after day, without adverse effect";

2. Threshold limit value/short term exposure limit (TLV/STEL, or simply STEL), defined as a 15-minute TWA exposure not to be exceeded during the workday even if TWA is in limits; STEL supplements TWA in cases where there are acute effects from a substance whose toxic effects are primarily of chronic nature;

3. Threshold limit value/ceiling (TLV/C) refers to the concentration that should not be exceeded during any part of the working exposure.

Exposure to particulate matter is normally expressed as TWA in terms of mg m\(^{-3}\). However, substances that may exert immediate effects have also STELs and TLV/C (e.g. acid mists containing sulfuric acid, sodium hydroxide, etc.).

Some substances have TLVs expressed size-selectively. The TLV for crystalline silica is expressed as the mass of the particles which belong to the fraction of respirable size. The TLV for asbestos is defined as the number of fibers belonging to a certain dimensional interval which is also considered a respirable fraction. Many other chemicals are suspected of having a potential hazard associated with the mass concentration of a certain size fraction. Consequently, more compounds are expected to have mass size-selective TLVs in the near future. The mass fraction for a dimensional interval (e.g. the mass of the respirable particles) refer to those particles that may be captured by a sampler in certain boundary conditions, as follows:

1. Inhalable particulates mass comprises particles that may be captured with 50% collection efficiency for a corresponding dimension of 100 µm; for particles with dimensions below 100 µm the collection efficiency increases with the decrease of the \(d_{ac}\); in the case of particles greater than 100 µm, the collection efficiency decreases with the increase of \(d_{ac}\).

2. Thoracic particulates mass, comprises particles that may be captured with 50% collection efficiency for a corresponding dimension of 10 µm; for particles with dimensions below 10 µm the collection efficiency increases with the decrease of the \(d_{ac}\); in the case of particles greater than 10 µm, the collection efficiency decreases with the increase of \(d_{ac}\).

3. Respirable particulates mass comprises particles that may be captured with 50% collection efficiency for a corresponding dimension of 4 µm; for particles with dimensions below 4 µm the collection efficiency increases with the decrease of the \(d_{ac}\); in the case of particles greater than 4 µm, the collection efficiency decreases with the increase of \(d_{ac}\). Equations followed by examples that illustrate these descriptions in quantitative terms may be found in ACGIH.\(^7\)

The explanations presented above rely on international conventions provided by the International Organization for Standardization/European Standardization Committee protocol. However, not all particulate measurements are made in accordance with these boundary conditions for samplers. In some countries, the median cut point for respirable particulate matter samplers is of 5 µm. Also, some older measurements performed in USA implied the use of samplers with a median cut point of 3.5 µm. Therefore, when comparing concentration measurements performed in different areas or at different intervals of time, it is recommended that additional data are obtained regarding the conditions in which the sampling was performed.

All exposure limits refer to personal exposure. Consequently, the analysis of toxins for compliance with TLVs must rely on personal sampling.

### 8 COMPARISON BETWEEN INDUSTRIAL AND NONINDUSTRIAL INDOOR ENVIRONMENTS

The size, shape, and chemical composition of particulates in the industrial environment strongly relate to the technological process involved. If there is no change of the operational parameters, the pollutants follow a reproducible pattern of concentration and distribution. The quality and quantity of home emissions depend on the inhabitants’ lifestyle and the general economic development. Therefore, it is difficult to establish a concentration profile.

In the industrial environment it is relatively easy to identify the sources that emit particulate matter.
By contrast, in the home and office environment the sources of emissions are small and diffuse. In general, the airborne concentrations of SPM in the home and office environments are lower than in the industrial workplaces.

For most toxins, the methods of chemical analysis for aerosols present in the two types of environments share the same techniques. Because the nonindustrial environment has lower levels of concentrations, the common way to adapt a method from industrial hygiene is to sample larger volumes of air. This is achieved either by increasing the sampling rate or the sampling period. The increase of the sampling rate by means of high volume samplers may be inadequate in some circumstances because they disturb the occupants of the building. On the other hand, longer sampling periods may result in loss of information regarding the fluctuating high concentrations. Some operations (e.g. cooking) release relatively large quantities of particles which may be underestimated because of the limited period of time in which they may be sampled. For such circumstances, it is necessary to use more sensitive, and thus more expensive, analytical techniques.

As stated before, the control of airborne particulates in the industrial environment rely on personal exposure. In nonindustrial environments it is difficult to perform personal exposure assessments. The house inhabitants are generally resistant to the requirement of carrying uncomfortable sampling equipment. The requisite for more expensive analytical methods may represent another drawback. Consequently, many exposure assessments in indoor environment use area sampling for the purpose of concentration measurements.

Carcinogens in indoor air include radioactive radon, a variety of organic compounds, several inorganic species, asbestos fibers, and a large number of chemical species associated with suspended particulate matter (SPM). Within these categories, carcinogens may be grouped by either chemical class and physical properties or by the methods used to measure them. Generally, measurement methods within a category are at least similar if not identical.

A typical measurement method includes procedures for sampling a known volume of air in a way that quantitatively collects the species of interest, transferring collected samples to a laboratory, and measuring species of interest in the samples using an appropriate validated analysis method. The sampling location may be in the breathing zone of a person (to measure personal exposure) or at a specific location in a building or room (to measure potential for exposure at that location). A sample may be collected very quickly (to obtain a snapshot of carcinogen concentration at a specific time) or very slowly over a period of hours, days, or weeks (to obtain an integrated or average carcinogen concentration).

The analysis method is essentially independent of the sampling location and sampling time, but collection of an adequate quantity of the species of interest is crucial. In general, radon is measured as radiation emitted from the sample; organic compounds are measured using gas or liquid chromatography with an appropriate detector; carcinogenic inorganic species are measured using atomic absorption spectroscopy (AAS) or atomic emission spectroscopy (AES); asbestos fibers are visually counted at high magnification; and particles are extracted with a solvent to quantitatively remove the species of interest, which are then measured using one of the organic or inorganic methods described above. Concentrations of the species of interest can then be calculated by dividing the quantity of each species measured in the collected sample by the volume of air sampled.

1 INTRODUCTION

Indoor air contains a complex mixture of chemical species in the vapor state and associated with airborne particulate matter. The number of chemical species present at one time can range into the thousands, especially if environmental tobacco smoke (ETS) is present. Concentrations of chemical species and particles, while usually quite low from an analytical perspective, may be significant, and the concentrations vary with location and with time within a given indoor air space. Some of the pollutants within this complex mixture appear to be harmless; but some are irritants, some are toxic, and some are known or suspected human carcinogens. Carcinogens are the focus of this article, although many of the monitoring approaches described here are also used for other species. (This article is an updated version of a paper by Peterson and Jayanty."
1.1 Carcinogens in Indoor Air

Pollutants, including known or suspected carcinogens, found in residential or nonoccupational indoor air come from a variety of sources. Some pollutants come from building materials, carpet, fabrics, adhesives, sealants, paints, stains, and other materials used to construct or maintain a home or other building; some pollutants are brought in or tracked in from outdoors; and some pollutants are generated by human activities such as smoking tobacco products, cooking, or using cleaning and personal care products. Even seemingly innocuous activities like sweeping or vacuuming floors and furnishing can fill the air in an indoor environment with respirable particles containing heavy metals tracked in from outdoors and carcinogenic species formed during heating and cooking activities.

1.1.1 Categories

For monitoring purposes, chemical species, including carcinogens and other pollutants, are often grouped on the basis of chemical class, chemical properties, or physical state. Species that can be measured by a single method are often treated as a group, but particularly hazardous members of a group may also be treated separately in more tightly focused monitoring programs. The categories of carcinogens in the following sections have been arranged in the general order of simplest to most complex, although there is considerable overlap.

Major categories include radon, organic compounds, inorganic species, asbestos, and particles. Radon and asbestos could have been included under inorganic species and particles, respectively, but methods to measure these two carcinogens are quite different from methods for measuring other carcinogens.

1.1.2 Physical States

Carcinogens in indoor air may exist in the gaseous, liquid, or solid state; they may be dissolved in liquid or adsorbed on to solid material associated with airborne particulate matter; or they may exist in any combination of these states. Some carcinogens, like radon and formaldehyde, exist primarily in the gaseous state, while others, like asbestos and some of the heavy metals, exist only in the solid state and occur in air as suspended particles or fibers. A third group of carcinogens, which includes low-volatility compounds like some pesticides and some components of ETS, may exist simultaneously in any combination of physical states.

1.1.3 Complex Mixtures

Indoor air is a complex mixture of gaseous species, suspended liquid and solid particles (SPM), and airborne fibers. Chemical species, including carcinogens, can be found in any or all of those states. Some individual chemical species may exist in the gaseous phase, be dissolved in suspended liquid particles, and be adsorbed on to solid particles at the same time, with molecules constantly moving from one state to another. The distribution of a particular species among the various physical states is determined by its vapor pressure (or volatility), its solubility in whatever liquid aerosol materials are present, and its affinity for active sites on the surface of whatever solid particles are present; and its concentrations in the gaseous, dissolved, and particle-bound states are affected by the temperature of the air. In addition, the sources of a species and the so-called "sinks" that remove the species from air are not evenly distributed, nor are source contribution rates and sink removal rates constant and perfectly balanced. Thus, the concentration of a species also varies with time and with location in a given indoor environment.

1.2 Sampling and Analysis

Measurement methods generally involve sampling indoor air to collect the species of interest and analyzing the collected sample to measure those species. The two parts, sampling and analysis, may be done on-site and essentially simultaneously to obtain more or less real-time measurements. Alternatively, collected samples may be transported to a laboratory for analysis.

Carcinogens are typically present in indoor air at extremely low concentrations.\(^2\) A sufficient volume of air must be sampled to yield an amount of the species of interest that is measurable by the chosen analysis method. Both the practical quantitation limit (PQL) of the analysis and an approximate or a maximum allowable (e.g., threshold limit value) concentration of the species of interest at the sampling location must be known before the volume of air that must be sampled can be determined.

1.2.1 Fundamental Objectives of Sampling

The fundamental objective of sampling is to obtain samples that contain representative concentrations of the species of interest for the purposes of the measurement. Samples are generally collected in a fashion that either mimics human exposure or provides data that can be related to human exposure. Whole-air samples can be collected in suitable containers, or the species of interest may be removed by some physical or chemical process from the air sample during collection.

Particles and fibers are typically collected on a filter, while gaseous species may be collected in a stainless steel canister or a Tedlar\textsuperscript{®} or aluminized bag, bubbled through a liquid-filled impinger, or concentrated on a
sorbent. Filters and sorbents remove and concentrate species of interest from a known volume of sampled air. Impingers are often used for collecting reactive or unstable species and generally are filled with a solution containing a derivatizing agent, which converts reactive species to stable derivatives. Species existing in both gaseous and particle-bound states are typically sampled using both a filter and a sorbent. Thus, collected samples may be whole-air samples collected in canisters or bags, particles or fibers collected on filters, or chemical species collected on sorbents or in a liquid-filled impinger.

The volume of air sampled (or sample volume) must be large enough to provide a measurable amount of the species of interest. On the other hand, the volume of air sampled is limited by the capacity of the sampling device or medium. Canisters, for example, generally have volumes of 6 L or less. Thus, using negative pressure to drive sampling into an evacuated canister limits the volume of air that can be collected to something less than the volume of the canister.

The volume of air that can be sampled through a filter is limited by increasing pressure drop across the filter as filter pores become clogged with collected particles or fibers. Samples are invalid if the pressure drop across the filter exceeds the maximum drop specified in the chosen sampling method.

The volume of air that can be sampled through a sorbent is limited by the weakness of the attachment of the species of interest to the sorbent. A sorbent is generally selected on the basis of its ability both to retain a species during sampling and to release the species for analysis. Thus, molecules of the target species that are trapped from the air moving over the sorbent subsequently move back into the gas phase, flow with the sampled air for a short distance, and then reattach to the sorbent. This process is repeated over and over again so that molecules of the target species migrate further and further into the sorbent bed. Breakthrough is said to have occurred if a measurable amount of the target species actually passes beyond the downstream end of the sorbent bed. The total volume of air sampled when breakthrough occurs is called the breakthrough volume. The volume of air sampled through a sorbent must be less than the breakthrough volume of the target species for that sorbent bed.

Whatever the method of sampling, the temperature, pressure, and volume of air sampled must be known for later calculations of species concentrations. In some cases, the humidity of the sampled air is also a factor.

1.2.2 Fundamental Objectives of Analysis

The fundamental objective of analysis is to provide reliable, accurate, and precise measurements of the species of interest. The analysis must provide an unambiguous measurement of the species without loss (e.g. through decomposition) or enhancement (e.g. through contamination) of the species. Often the species of interest must be separated from other species present in collected samples prior to measurement. In this situation, the analytical system may be used to both isolate and measure species of interest.

An appropriate analytical system is one that responds in a characteristic and quantifiable way to species of interest. In modern instruments, the response of an analytical system to a species is often converted into an electrical signal with a magnitude that is directly related to the amount of the species present in the detection device of the instrument. In such systems, the response of the instrument to the species in a collected sample is compared to the response of the instrument to standards containing known amounts of the species. Analysis of standards containing different amounts of a species and the subsequent plotting of instrument response versus amount of species analyzed is referred to as calibration. The range of the calibration (or range of amounts of species in the standards analyzed for the calibration) must bracket the amounts of species measured in collected samples.

1.3 Basic Monitoring Approaches

A monitoring approach must be chosen based on the goals of the desired measurement, the sampling and analysis methods available for the species of interest, and the concentrations of the species of interest in the indoor environment to be monitored. Some of the choices to be considered in designing an appropriate monitoring plan are described below.\(^3\)

1.3.1 Selection of Monitoring Location

Because concentrations of species vary with location and with time within a given indoor environment and because people often move in and out among a variety of environments, monitoring or sampling locations must be carefully chosen to ensure that measurements are meaningful. The selection of a monitoring or sampling location is based on the purpose of the measurement. To measure the exposure of a particular person to a particular species of interest, monitoring or sampling is done near the breathing zone of the person during his or her usual daily activities. To measure the concentration of a particular species in a particular indoor environment, monitoring or sampling is done at fixed points within that environment. In survey studies, many people and many indoor environments are monitored or sampled according to a specific protocol, which details the sampling and analysis parameters.
1.3.2 Real-time Measurements versus Laboratory Analysis of Samples

So-called “real-time” measurements require that both sampling and analysis be done on-site. The term “real-time” is somewhat misleading because there is often a lag time between sampling and analysis, particularly if the target species must be concentrated prior to measurement. “Real-time” usually means that measurement results are available a short time (a few minutes to an hour or so) after the sample is taken. Real-time measurements generally require a dedicated on-site sampling and analysis system or an automated monitor.

Analyzing collected samples in a laboratory means that measurement results will be available within a few days or weeks. The advantages of laboratory analysis include a controlled analytical environment, the availability of more sophisticated equipment, and the ability to analyze samples from many locations on a single instrument.

1.3.3 Grab Sampling, Integrated Sampling, and Continuous Sampling

Samples of indoor air may be collected quickly over a very short time or at a slower sampling rate over an extended period of time. The advantages of laboratory analysis include a controlled analytical environment, the availability of more sophisticated equipment, and the ability to analyze samples from many locations on a single instrument.

A grab sample, which may be collected by simply opening a valve on an evacuated canister for a few seconds, represents a snapshot of the air at the sampling location at the specific time the sample was taken. A series of grab samples taken at a single location at specific time intervals can be used to determine variations in concentrations of species over time. An integrated sample, which is collected at a fixed sample flow rate over an extended time period, can be used to determine average concentrations of species over time. Integrated samples are usually used to measure individual human exposure. Continuous sampling devices can provide near-real-time measurements, but such devices require a dedicated analytical system at the sampling site.

1.3.4 Active Sampling versus Passive Sampling

In active sampling, air is drawn through or into a sample collection device by means of a pump or an evacuated canister. The volume of air sampled can be calculated by multiplying the flow rate through the sampling pump by the sampling time or from the pressure increase inside and the volume and temperature of the canister. Active sampling can be used for essentially all of the carcinogens that occur in indoor air, although samples collected in this way may not provide the best available estimates of human exposure.

In passive sampling, gaseous species diffuse through a permeable membrane and interact with, or are trapped by, some medium (e.g., a sorbent). Passive sampling does not require a pump and represents a fairly inexpensive way to obtain integrated samples. Passive samplers are also small and unobtrusive.

1.4 Overview

Monitoring approaches used to measure various categories of carcinogens in indoor air are presented below. Some of the methods were developed to measure species in workplace air or in ambient (outdoor) air but should, in principle, also be applicable to measurement of the same species in indoor air. The categories addressed include radon, organic compounds, inorganic species, asbestos, and particles. Methods sometimes span several categories; for example, radon decay products, SVOCs and nonvolatile organic compounds, and inorganic species are associated with particles.

2 RADON

Radon is considered a carcinogen because of its radioactivity. The actual harm to human health comes from the radioactivity of the decay products of radon. Radon is a gas and, if inhaled, is not retained well by the lungs. When radon atoms undergo radioactive decay, the decay products do not remain in the gas phase but become attached to airborne particles, which, if inhaled, can be retained in the lungs indefinitely. It is the particle-bound radon decay products that are actually the cause of the increased risk of lung cancer attributed to radon.

2.1 Overview

Concentrations of radon and radon decay products (or progeny) in indoor air vary with location and with time. The primary isotope of interest, radon-222 or \(^{222}\text{Rn}\), its decay products are part of the radioactive decay series leading from a naturally occurring, long-lived radioactive isotope (uranium-238) to a stable isotope (lead-206). A portion of this series, showing the formation of radon-222 and its decay products of interest (polonium-218, lead-214, bismuth-214, and polonium-214), is shown in Figure 1. The primary decay mode of an isotope is denoted by the type of radiation associated with fission of that isotope. An \(\alpha\)-particle is a helium-4 nucleus (\(\text{He}^{2+}\))
A β-particle is formed when a neutron in the nucleus of an atom is converted to a proton, which remains in the nucleus, and a high-energy electron (the β-particle), which is ejected from the nucleus. Loss of a β-particle does not affect the mass number of the atom but increases the atomic number by one. In both types of radioactive decay, an atom of one element is changed into an atom of another element because the atomic number changes. Emission of γ-rays, which are high-energy photons, during radioactive decay does not affect the mass number or the atomic number of an isotope. The half-life of an isotope is the time required for half of the atoms of that isotope in a sample to undergo radioactive decay.

A second radon isotope, radon-220 (sometimes called thoron) or $^{220}_{86}$Rn, and its decay products are part of the radioactive decay series leading from another naturally occurring, long-lived radioactive isotope (thorium-232) to a different stable isotope of lead (lead-208). A portion of this series, showing the formation of radon-220 and its decay products of interest (polonium-216, lead-212, bismuth-212, and polonium-212), is shown in Figure 2. Radon-220 and its decay products, while just as deadly as isotopes associated with radon-222, pose a lower risk to human health because of the short (55.6 s) half-life of radon-220, which limits its time in the gas phase and therefore its migration distance.

### 2.1.1 Radon

Of all of the isotopes in the two decay series, only the radon isotopes are gases at ambient conditions. Existence as a gas, which allows radon to migrate from soil or rock into indoor air in the first place, provides a distinguishing characteristic that can be used to separate radon from other radioactive species.

#### 2.1.2 Radon Decay Products

When atoms of radon gas undergo radioactive decay, the newly formed polonium atoms (and any subsequently formed polonium decay products) immediately condense or attach on to any surface with which they come into contact. In indoor air, that surface is usually associated with airborne particulate matter.

### 2.2 Monitoring Methods

Monitoring of radon and radon decay products in indoor air is complicated by the nuclear instability of the target species. With half-lives ranging from almost 4 days for radon-222 to a fraction of a second for polonium-216, measurements based on emitted radiation must be made shortly after collection.

Indoor air may be sampled for radon or radon progeny measurements by grab sampling, integrated sampling, or continuous sampling. Separation of radon from progeny may be accomplished by allowing the radon to diffuse through a passive barrier (e.g. foam rubber) that does not allow the passage of particulate material containing the radon progeny.

Methods for measuring radon and radon progeny actually measure emitted radiation. In the absence of other radioactive species, emitted radiation is directly proportional to the concentration of radon and radon progeny in the sample. The emitted radiation may be in the form of α- or β-particles or γ-rays, all of which can be measured with appropriate instrumentation.

Table 1 provides an overview of applications and sensitivities of devices used to measure radon and its decay products.

### 2.2.1 Direct Measurement

Direct measurements are made with either a scintillation cell or an ionization chamber. Both approaches can be used in continuous monitoring or to analyze grab samples. The inside walls of a scintillation cell are coated with a phosphorescent material, which emits light when struck by an α-particle from decaying radon. The light from the phosphor is measured with the aid of a photomultiplier tube. The measurement is used to count the scintillations due to radioactive decay within the cell. The cell can be used to measure radon in grab samples or in a flow-through mode for continuous measurements. Progeny can be excluded (as described above) to allow only radon into the cell. In this mode, radon decaying within the cell forms progeny that attach to the walls.

\(^a\) Adapted from Cothern and Smith, Jr.\(^5\)

\(^b\) With radon progeny collected on or close to a scintillator or thermoluminescent detector chip.

\(^c\) A sensitivity less than the value shown is generally achievable, depending on the specific instrument used (1 pCi L\(^{-1}\) = 37 Bq m\(^{-3}\)).

\(^d\) Three typical purposes for the measurement include:
- screening – to detect rapidly and inexpensively the occurrence of high radon concentrations;
- diagnostic – to measure such specific parameters as short-term spatial and temporal concentration variations, relationship with other factors (e.g. ventilation rate), equilibrium fraction of each of the radon progeny, or the effect of remedial actions;
- large-scale survey – to obtain a large number of time-averaged measurements aimed at evaluating the exposure of the public.

of the cell and subsequently further decay. This decay of progeny within the cell also contributes to the scintillation measurement and must be taken into account in flow-through mode.\(^6\)

In an ionization chamber, the electric field between two electrodes is altered when the decay of radon or progeny ionizes some of the air molecules in the chamber. The current flow between the two electrodes is measured with an electrometer, and the measurement is converted into concentration of radon or radon decay products.

#### 2.2.2 Passive Barrier Method

In the passive barrier method, radon decay products are collected on or in close proximity to a scintillator or a thermoluminescent dosimeter (TLD) chip. The scintillator allows continuous measurement of decay products, and the TLD chip, which is usually made of lithium fluoride or calcium fluoride, provides an integrated measurement.

#### 2.2.3 Two-filter Method

In the two-filter method, sampled air is drawn through a small tube that is equipped with filters on both ends. The upstream (or entrance) filter removes radon decay products from the sample allowing only radon to pass into the tube. Some of the radon undergoes radioactive decay while it is transversing the tube, and the resulting polonium-218 and any subsequent decay products formed in the tube are collected on the downstream (or exit) filter. After sampling, the downstream filter is removed and the collected decay products counted by measurement of \(\alpha\)-decays. This method can be used in a continuous or integrative mode by placing a TLD chip at the downstream filter during sampling.

#### 2.2.4 Passive Sampling Devices

Common passive sampling devices include charcoal canisters and \(\alpha\)-track detectors. In a charcoal canister, radon is collected by adsorption on to activated charcoal. Radon collected on charcoal can be measured in several ways. In one approach, radon is de-emanated from charcoal into a scintillation cell and measured by counting \(\alpha\)-decays. In another approach, the charcoal is heated to desorb collected radon, which is then measured by counting \(\gamma\)-emissions. In a third approach, the charcoal is placed in a liquid scintillation fluid and measured by counting scintillation events.

An \(\alpha\)-track detector contains a small slab of material that sustains microscopic damage when struck by an \(\alpha\)-particle. The microscopic gouge marks or tracks made by the \(\alpha\)-particles are enlarged by chemical etching and visually counted with the aid of a microscope. An \(\alpha\)-track
detector can be exposed for up to a year before it is etched and counted.

3 ORGANIC COMPOUNDS

3.1 Overview

Organic compounds are simply compounds containing the element carbon. The vast majority of pollutants that may be present in indoor air are organic compounds.

3.1.1 Classification of Organic Pollutants

In addition to the usual classification of organic compounds by functional group (e.g., alcohols, ketones, aromatic compounds, halogenated compounds, etc.), organic pollutants in indoor air are often classified on the basis of boiling points. The boiling point of a compound is indicative of the compound’s volatility, which to a large extent determines the distribution of the compound between gaseous and condensed phases. A general classification scheme based on boiling points is shown in Table 2. The boiling point ranges assigned to various classes are somewhat arbitrary, and compounds with boiling points outside the range for a particular class may be included with that class in a particular study or for analysis by a particular analytical method.⁷

VVOCs exist almost completely in the gaseous state in indoor air. Some VVOCs actually have boiling points below room temperature. VOCs can exist in the gaseous state in air at relatively high concentrations. SVOCs are much less volatile and tend to have low gas-phase concentrations, but SVOCs can exist at high concentrations in liquid aerosol droplets and on solid particles. Some organic compounds, often called particulate organic matter (POM), have such low volatilities that they exist in air almost exclusively as or on particles.

3.1.2 Complexity of Organic Mixtures

Measuring concentrations of specific organic compounds in indoor air can be quite a formidable challenge because of the complexity and variability of the indoor air matrix. Literally thousands of organic compounds are present in such complex mixtures as ETS. If suspended liquid- and solid-phase particulate matter is present, the VOCs and SVOCs exist in a complex, constantly changing distribution among gaseous, condensed, dissolved, and adsorbed states.

3.2 General Monitoring Methods for Organic Compounds

Monitoring of organic compounds is generally accomplished in three steps: collection, separation, and measurement.

3.2.1 Collection

VOCs in indoor air are collected either as whole-air samples in evacuated stainless steel canisters or by passing a measured volume of sampled air through a solid sorbent, which removes compounds of interest from the sampled air.⁸ While both approaches to collection work well for time-averaged or integrated samples (up to 24 h), evacuated canisters can also be used for grab sampling. Because the sample is collected over a very short time interval (typically a few seconds to a minute), grab sampling can be used to obtain a snapshot of pollutant concentrations. A series of grab samples can be used to measure concentration variability over time. Whole-air samples collected in a canister must be concentrated, usually by passing a known amount of air from the canister through a cryogenic or sorbent-based preconcentration unit, prior to analysis.

Sorbents are granular solids and are packed in glass tubes in sections held in place by plugs of glass wool.

* Polar compounds generally have higher boiling points than nonpolar compounds of similar molecular weight.
Sorbents trap or collect compounds of interest from sampled air as it is drawn through the tube. Sorbents and the stationary phases used in chromatography (discussed in the next section) operate according to the same basic mechanisms. In some applications, several different sorbents may be packed in separate sections within the same glass tube. These multisorbent tubes are often used if the target compounds span a wide range of polarities or molecular sizes.

The ideal sorbent for a given set of target compounds will completely trap those compounds from a large volume of sampled air without loss (or breakthrough) and will completely release those compounds when either heated (thermal desorption) or treated with a solvent (solvent desorption). Real sorbents, of course, generally have collection efficiencies and desorption efficiencies that are less than 100% for most organic compounds. Some of the more common sorbents used for collecting organic compounds in indoor air are described in Table 3.

With thermal desorption, the entire sorbent tube is quickly heated to a high temperature (300 °C or so) and desorbed compounds are backflushed off the sorbent in the tube with a flow of helium (or other carrier gas). The entire sample is then used in a single analysis. Although only a single measurement for each compound is obtained per tube, the method limit of quantitation (MLOQs), which take into account the fraction of a collected sample that is actually analyzed) are much lower because all of each target compound in the sample is delivered to the analysis system at one time.

With solvent desorption, the sorbent sections from each tube are desorbed separately with one or more suitable solvents, and the resulting solutions analyzed separately. Concentration comparisons can then be made to see if any of the target compounds passed through the front section of sorbent and were collected on some downstream section. Solvent desorption offers the advantage of multiple analyses of each desorption solution but the MLOQs are typically higher because only a small fraction of the collected sample is actually analyzed.

Reactive or polar (heteroatom-containing) VOCs are usually collected in a glass impinger filled with a solvent in which the VOCs are very soluble and perhaps containing, if one or more of the target VOCs is reactive, a derivatizing agent. The derivatizing agent converts reactive VOCs into stable derivatives. Derivatives are often solvent-extracted from the impinger solution prior to analysis.

### 3.2.2 Separation

Either gas chromatography (GC) or high-performance liquid chromatography (HPLC) is used to separate organic compounds. As a general rule, thermally stable gaseous, volatile, or semivolatile compounds are separated by GC; and reactive or nonvolatile compounds are separated by HPLC. Both involve differential migration of organic compounds moving in a mobile phase across a stationary phase. The time required for a particular compound to pass through a chromatography column is referred to as the retention time for that compound. The goal of chromatographic separation is to isolate each compound of interest from all other species present so that the pure compounds can be measured one by one as they exit (or elute from) the chromatography column.

In GC, the mobile phase is a gas and the stationary phase is a solid or high-boiling liquid. In modern GC columns, the stationary phase is usually chemically bonded to a solid support or to the inside of a long (30–60 m) capillary column. Temperature programming of the column is used to speed the analysis without jeopardizing the complete separation of the compounds of interest from other species present.

In HPLC, the mobile phase is a liquid or a solution. Unlike GC, the composition of the mobile phase is crucial

to HPLC separations. Solvent programming, or changing the ionic strength of the mobile phase during analysis, is used in a fashion analogous in many ways to the use of temperature programming in GC.

### 3.2.3 Measurement

Measurement of organic compounds exiting a GC or HPLC column is accomplished by means of a detector, which generates an electrical response when a compound passes through it. The magnitude of the electrical response is proportional to the amount of the compound present in the detector. From a measurement perspective, concentrations of individual organic compounds in indoor air are usually quite low. The analytical limit of quantitation (ALOQ) for the measurement of a particular compound is usually expressed as the minimum mass of that compound that results in a measurable and reproducible electrical response on the detector used for the measurement. The ALOQ is usually estimated as the mass of compound required to give a detector response that is 10 times the standard deviation of detector responses to at least seven replicate measurements for a mass of the compound that is slightly above the ALOQ. Often, organic compounds in indoor air must be concentrated to provide sufficient mass of each target compound to give detector responses above the individual ALOQs in a given analysis. Concentrating of compounds is usually accomplished by passing sampled air through a collection medium, usually a solid sorbent, and subsequently analyzing the collection medium.

Table 4 lists some common GC detectors and approximate detection limits and applications for each. Some of the detectors are universal (respond to all compounds), and some respond only to compounds that meet certain criteria. All of the detectors rely on retention time for compound identification, and, for all but one of the detectors, retention time is the only evidence available for compound identification.

Only the mass spectrometric detector (MSD) allows unambiguous identification of compounds. In an MSD, a portion of the column effluent passes through an ionization chamber, which ionizes molecules in the effluent with sufficient energy to cause some of them to break into fragments. The fragments are separated on the basis of their mass-to-charge (m/z) ratios, and the relative abundances of the fragments are measured. In scan mode, relative abundances are monitored for a wide range of m/z values for the entire chromatogram. This provides a three-dimensional array of data (time, m/z value, and relative abundance). A mass spectrum, which is a plot of m/z value versus relative abundance, can be displayed for any given time in the chromatogram. Identification of a compound is accomplished by electronically matching the mass spectrum measured during analysis at the known retention time for the compound to mass spectra stored in an on-line library. In single-ion monitoring (SIM) mode, only selected m/z values are measured. Increased sensitivity is obtained in SIM mode because the instrument’s data collection resources are focused on monitoring only one or, at most, a few m/z values instead of the several hundred values monitored in scan mode.

Common HPLC detectors include refractometers and ultraviolet (UV) detectors, including the photodiode array (PDA) detector. The PDA detector monitors UV light absorption over a range of wavelengths to give a three-dimensional data set that can be used for compound identification.

### 3.3 Organic Carcinogens of Particular Concern

Organic compounds that are classified as known or suspected human carcinogens and that may be present in indoor air include benzene (CAS 71-43-2), p-dichlorobenzene (CAS 541-73-1), carbon tetrachloride (CAS 56-23-5), chloroform (CAS 67-66-3), methylene chloride (CAS 75-09-2), formaldehyde (CAS 50-00-0), polycyclic aromatic hydrocarbons (PAHs), and some pesticides. Except for the last three, all of the compounds in the list can be measured using methods described above.

3.3.1 Formaldehyde

Formaldehyde is a fairly reactive VVOC that is very difficult to measure directly, and devising an appropriate sampling strategy is not always straightforward.\(^{11}\) Formaldehyde is usually converted to a stable derivative (often by reaction with pararosaniline or 2,4-dinitrophenyl-hydrzone) by bubbling the sampled air through an aqueous solution of the derivatizing agent or by pulling the sampled air through a cartridge containing the derivatizing agent coated on some solid support, and the derivative is measured by some calorimetric, HPLC, or GC method.\(^{8}\)

Passive badge monitors are also used to sample formaldehyde in air. The US Occupational Safety and Health Administration (USOSHA) Method ID-205 provides for sampling using a passive badge containing bisulfite-impregnated paper. Samples are desorbed with deionized water, the desorption solution is acidified and treated with chromatographic acid, and the color complex is analyzed using a UV spectrophotometer at a wavelength setting of 580 nm. Method ID-205 has a quantitative detection limit of 0.11 parts per million of formaldehyde in air with a 4-h badge exposure time.\(^{12}\)

3.3.2 Polycyclic Aromatic Hydrocarbons

PAHs are SVOCs containing only carbon and hydrogen with molecular structures composed of multiple, fused 5- and 6-carbon aromatic rings. Carcinogenic PAHs that may be present in indoor air include benzo[a]pyrene (CAS 50-32-8) and benzo[b]fluoranthene (CAS 205-99-2). As a group, PAHs have high melting and boiling points and very low vapor pressures. Consequently, PAHs exist primarily as or on particles and are typically collected on filters. Concentrations of PAHs in air are generally extremely low (1–100 µg per 1000 m³ of air) so that very large volumes of air must be sampled to obtain sufficient mass of each PAH for measurement. Although a variety of methods have been used to successfully measure PAHs,\(^{13}\) the approach of choice is most often extraction from the filter using an appropriate solvent, separation by GC, and measurement with a flame ionization detector (FID) or with an MSD. The latter approach allows confirmation of the identity of the PAHs in the sample.\(^{8}\)

3.3.3 Pesticides

Organic pesticides are SVOCs that are classified on the basis of use and not molecular structure. Pesticides that are known or suspected carcinogens and that may be found in indoor air include heptachlor (CAS 76-44-8), heptachlor epoxide (CAS 1024-57-3), and hexachlorobenzene (CAS 118-74-1). Pesticides in indoor air are found condensed or adsorbed on to dust particles and in the vapor state. Pesticides in the vapor state are collected on a sorbent, desorbed with a solvent, and analyzed by GC/MSD. Pesticides in airborne dust are collected on a filter and extracted with a solvent. The solvent solution is then concentrated and the resulting concentrate analyzed by GC/MSD.\(^{14}\) In some applications, an electron-capture detector can provide greater analytical sensitivity for pesticides containing chlorine or fluorine.\(^{8}\)

4 INORGANIC SPECIES

4.1 Overview

Inorganic carcinogens include some of the heavy metals and their compounds. The heavy metals of primary concern are arsenic (CAS 7440-38-2) (salts, arsenates, and arsениtes), beryllium (CAS 7440-41-7), cadmium [oxide (CAS 1306-19-0) fume, bromide (CAS 7789-42-6), and chloride (CAS 10108-64-2)], chromium (hexavalent) (CAS 18540-29-9), nickel [carbonyl (CAS 13463-39-3) and subsulfide (CAS 12035-72-2)], and selenium [sulfide (CAS 7446-34-6)].

4.1.1 Behavior of Ionic Species

Most, but not all, of the inorganic carcinogens listed above exist as salts. Because of the omnidirectional nature of ionic chemical bonds, salts tend to exist as high-melting solids. Such salts are found in air only as a component of SPM.

4.1.2 Oxidation States

The oxidation state of an element in a compound is assigned by a set of rules that allot valence (or outermost) electrons, which are involved in chemical bonding, to the more electronegative (or electron-attracting) element and leave the less electronegative element electron deficient. Thus, the more electronegative element is assigned a negative oxidation state (more electrons assigned than protons in the nucleus), and the less electronegative element is assigned a positive oxidation state (fewer electrons assigned than protons in the nucleus). Metal atoms in compounds are usually assigned positive oxidation states. Oxidation state is a factor in the carcinogenicity of a metal. Hexavalent chromium has an oxidation number of +6 and is classified as a carcinogen, while chromium in other oxidation states (e.g. +3) is not.

4.2 General Monitoring Methods for Inorganic Species

Standard methods have been developed for measuring individual metals in workplace atmospheres. Those
methods should also be appropriate for indoor air. In some cases, more accurate methods of collection and analysis have been reported, but they have not yet been validated or accepted as standard methods.

4.2.1 Collection

Inorganic salts, which exist in air as particulate matter, are collected on filters. Metals are removed from filters by acid digestion and the resulting solution analyzed. Volatile inorganic compounds are usually collected in liquid-filled impingers.

4.2.2 Measurement

Measurement of metals in nonvolatile species is usually accomplished by some type of AAS or AES. More sophisticated instruments, including inductively coupled plasma atomic emission spectroscopy (ICP-MS) or inductively coupled plasma mass spectrometry (ICP-MS), can measure many different metals in a single analysis. This type of measurement can often be carried out on an aliquot of the sample with no separation of species. Unfortunately, because of chemical changes caused by the rather severe analytical conditions, such approaches measure only the total amount of a metal present and cannot distinguish between different oxidation states of the same metal.

Measurement of a metal in a particular oxidation state, for example, chromium (VI), requires that the species be separated from the matrix by ion chromatography (IC) or some other means, or the species must exhibit some chemical property that is unique among the components of the matrix.

4.3 Inorganic Carcinogens of Particular Concern

The species listed in Table 5 represent inorganic carcinogens that may be present in air and that are of particular concern. Table 5 gives an overview of some published methods for collecting and measuring carcinogenic metals in air and the analyte actually measured. (12, 15, 16) Brief descriptions of several general methods for metals in air are given below.

4.3.1 General Method

The US NIOSH has developed a single method (Method 7300) that can be used to measure 29 elements, including all of those addressed here except nickel. \(^{15}\) Particulates, including the metal salts, are collected on a cellulose ester membrane filter and analyzed by ICPAES.

USOSHA has developed two methods for measuring concentrations of elements, including the carcinogenic metals of concern here, from metal and metalloid particulates in workplace atmospheres. Both USOSHA Methods ID-121 and ID-125G provide for collection of airborne particulates on a mixed-cellulose ester filter. USOSHA Method ID-121, which can be used to measure three of the six carcinogenic metals, requires analysis by AAS; and USOSHA Method ID-125G, which can be used to measure all six carcinogenic metals, requires analysis by AES. \(^{12}\)

4.3.2 Arsenic

NIOSH Method 7900 measures arsenic and its compounds as total arsenic. \(^{15}\) The sample is collected on a cellulose ester membrane and analyzed by AAFA. The estimated limit of detection for this method is 0.02 µg per sample.

USOSHA Method ID-105 measures arsenic and its compounds as total arsenic. If volatile inorganic arsenic compounds (arsine, for example) are present, a chemically treated backup pad is added to the usual mixed-cellulose ester filter used for collection of airborne particulates. Arsenic is removed from the collection media by acid-digestion, and the resulting solution analyzed by AAS using a heated graphite atomizer (HGA). The method has a quantitative detection limit of 0.01 µg mL\(^{-1}\), which corresponds to a concentration of 0.0005 mg m\(^{-3}\) of arsenic in air for a sample volume of 480 L of air and a solution volume of 25 mL. \(^{12}\)

Total arsenic in air can also be determined by USOSHA Method ID-125G. Airborne particulate matter is collected on a mixed-cellulose ester membrane filter, and arsenic is measured using ICPAES. The nonoptimized quantitative detection limit is 5.7 µg arsenic assuming a solution volume of 50 mL. \(^{12}\)

4.3.3 Beryllium

Beryllium also occurs in air as a component of SPM, but beryllium compounds are sufficiently volatile to be analyzed by GC, although a pretreatment step offsets some of the advantages of using GC. Beryllium is collected on a membrane filter and can be measured by inductively coupled plasma emission or by atomic absorption–graphite furnace. The limit of detection for the latter, which is used in NIOSH Method 7102, is 0.005 µg per sample. \(^{15}\)

Beryllium in air can also be measured using USOSHA Method ID-125G. Airborne particulate matter is collected on a mixed-cellulose ester membrane filter, and beryllium is measured using ICPAES. The quantitative detection limit is 0.043 µg beryllium assuming a solution volume of 50 mL. \(^{12}\)

4.3.4 Cadmium (Oxide, Bromide, and Chloride)

According to NIOSH Method 7048, cadmium compounds in air can be collected on a cellulose ester membrane filter and analyzed by atomic absorption with flame. The estimated limit of detection is 0.05 µg per sample. \(^{15}\)

Three methods for measuring cadmium in air have been validated by USOSHA. USOSHA Method ID-189 requires collection of SPM on a mixed-cellulose ester membrane filter and analysis by either FAAS or flameless AAS using an HGA. The Method ID-189 quantitative detection limit for cadmium in air is 0.70 µg m\(^{-3}\) for a 200-L sample by FAAS and 0.025 µg m\(^{-3}\) for a 60-L sample by AAS/HGA. USOSHA Method ID-121 requires collection of SPM on a mixed-cellulose ester filter and analysis by AAS or AES. The Method ID-121 analytical detection limit for cadmium in solution is 0.004 µg mL\(^{-1}\). USOSHA Method ID-125G requires collection of SPM on a mixed-cellulose ester membrane filter, and cadmium is measured using ICPAES. The quantitative detection limit is 0.47 µg cadmium assuming a solution volume of 50 mL. \(^{12}\)

4.3.5 Hexavalent Chromium

Chromium (VI) is usually collected from air on filters of cellulose, polyethylene, polystyrene, PVC, or glass and may be separated from matrix materials by IC. In NIOSH Method 7600, samples are collected on a PVC membrane filter and chromium is measured by VIS. The estimated limit of detection by Method 7600 is 0.05 µg per sample. \(^{15}\) In USOSHA Method ID-215, SPM is collected on a PVC filter and chromium (VI) is measured by IC with UV/VIS detection. The quantitative detection limit for chromium (VI) by Method ID-215 is 0.0030 µg m\(^{-3}\) in a 960-L air sample. \(^{12}\)

4.3.6 Nickel (Carbonyl and Subsulfide)

Most compounds of nickel exist in ambient air as a component of SPM and may be collected on a filter. Unfortunately, nickel carbonyl is quite volatile and cannot be collected efficiently on a filter. Volatile compounds of nickel are usually collected in liquid-filled impingers. Analytical methods for nickel include AAS with and without flame, X-ray fluorescence spectrometry, inductively coupled argon plasma spectroscopy, calorimetry, spark
source mass spectrometry, neutron activation analysis, and flame emission spectrophotometry.

USOSHA Methods ID-121 and ID-125G, which are described above, also have been validated to measure total nickel in airborne particulate matter. The analytical detection limit for nickel in solution by Method ID-121 is 0.1 µg mL⁻¹, and the quantitative detection limit by Method ID-125G is 2.0 µg of nickel based on a 50-mL solution volume.¹²

### 4.3.7 Selenium (Sulfide)

Selenium may be measured by NIOSH Method 7300, which is described above, with an estimated limit of detection of 1 µg per sample.¹⁵ USOSHA Method ID-125G may be used as a screening method for selenium with an estimated quantitative detection limit of 11 µg based on a 50-mL solution volume.¹²

## 5 ASBESTOS

### 5.1 Overview

Asbestos (CAS 1332-21-4) is a group of naturally occurring fibrous minerals that are nonflammable and chemically unreactive. Unfortunately, the inertness and chemical stability that made asbestos popular as a component of insulation materials and floor and ceiling tiles are the properties that keep inhaled asbestos fibers intact in lung tissue for decades. Mineral forms of asbestos include actinolite (CAS 13768-00-8), amosite or grunerite (CAS 12172-73-5), anthophyllite (CAS 17068-78-9), chrysotile (CAS 12001-29-5), crocidolite (CAS 12001-28-4), and tremolite (CAS 14567-73-8).

### 5.2 Sampling Airborne Fibers

Fibers are typically collected on a cellulose ester or polycarbonate filter, transferred to a slide, and measured visually under relatively high magnification. The volume of air sampled and the surface area of the filter are used in calculating the concentration of fibers.

### 5.3 Laboratory Analysis Methods

Asbestos fibers in collected samples are magnified for counting by either phase contrast microscopy (PCM), scanning electron microscopy (SEM), or transmission electron microscopy (TEM). Table 6 gives a comparative summary of the three types of microscopy. The extremely small size of airborne asbestos fibers makes them difficult to distinguish from other natural and man-made fibers. Only TEM offers definitive identification of asbestos fibers.

- **a** See USEPA.¹⁸
- **b** Diameter of thinnest fiber visible.
- **c** All fibers with a length > 5 µm and with a length-to-width ratio ≥ 3:1 are counted.

### 5.3.1 Phase Contrast Microscopy

NIOSH Method 7400 describes a procedure for collecting and counting asbestos and other fibers by PCM. Fibers are collected on a 0.45–1.2-µm cellulose ester membrane filter. The volume of air sampled is adjusted to give 100–1300 fibers per square millimeter of surface area on the filter. A section of the filter is placed on a glass microscope slide, and, after some additional sample treatment, positioned under the lens of a positive phase contrast microscope equipped with a Type G–22 Walton-Beckett graticule (100-µm diameter field of view). Magnified fibers in randomly selected grid positions are then manually counted according to rigid counting rules. Fiber concentration (fibers per liter of air) in the sampled air is computed from the average fiber density (fibers per square millimeter of surface area) on the filter, the total effective collection area of the filter (in square millimeters), and the volume of air sampled (in liters).¹⁵ USOSHA Method ID-160 describes a similar procedure.¹²

Although it is used to estimate asbestos concentrations in air, PCM does not allow differentiation between asbestos and other fibers. All fibers and particles meeting the criteria set out in the counting rules (i.e. longer than 5 µm and with a length-to-width ratio greater than or equal to 3:1) are counted. Fibers with diameters less than about 0.25 µm are not detected by PCM.

### 5.3.2 Scanning Electron Microscopy

At present, there is no standard method for the measurement of airborne asbestos using SEM, but procedures for doing so have been developed. Typically, fibers are collected on a 0.4–0.8-µm pore-size polycarbonate (or cellulose ester) filter and carbon-coated directly on the filter. The sample is then transferred to a grid for measurement. The fiber substrate is relatively thick, and the electrons bombarding the specimen during visual analysis
are scattered and reflected rather than transmitted. Only fibers with a diameter of about 0.20 µm or larger can be detected visually by SEM because the scattered and reflected electrons are detected as noise by the microscope. SEM is more specific for asbestos than PCM, but it is not definitive. However, analysis by SEM is much less expensive and more widely available than analysis by TEM.

5.3.3 Transmission Electron Microscopy

NIOSH Method 7402 describes a procedure for measuring asbestos fibers in air by TEM, which is designed to complement results obtained by the PCM method (NIOSH Method 7400) described above. Fibers are collected on the same kind of filter and in the same manner as in the PCM method. Following slide preparation, fibers are identified as asbestos (from fiber morphology, selected area electron diffraction patterns, and energy dispersive X-ray analysis); measured; and counted at a magnification of 20,000×.

Lack of availability, cost, and the time required for analysis are the major disadvantages of TEM analysis. The procedure can be broken down into three levels to reduce the cost and time required for analysis: (1) identification of asbestos for screening purposes; (2) elemental analysis of selected fibers for regulatory action; and (3) quantitative analysis of a few representative fibers for confirmatory analysis.

6 PARTICLES

6.1 Overview

Respirable particles (i.e., particles with aerodynamic diameters of 10 µm or less) represent not only a source of respiratory irritation and allergic response but a pathway for delivery of significant amounts of chemical species, including nonvolatiles, directly to the lungs. Virtually all known or suspected carcinogens can be delivered to the lungs and ultimately to the bloodstream through inhalation of particles containing those species. It is often the chemical species attached to particles, not the particles themselves, that pose the greater threat to human health. Table 7 provides an overview of sampling devices and analytical methods that are used to collect and measure particles in industrial workplaces. Only those devices and methods that are most applicable to monitoring human exposure to carcinogens in indoor air are discussed below.

6.2 Sampling Airborne Particles

Particles in air are collected on a filter, usually with a pore size of about 5 µm. Filters may be made from an organic polymer (e.g., Teflon® or PVC) or from glass fibers. The filter is weighed before and after sampling to determine the mass of particles collected. In industrial workplaces, recommended sample volumes range from 1 to more than 1000 L, depending upon the concentration of particles or the chemical species of interest attached to them present in the sampled air. Volumes of indoor or residential air that must be sampled should be on the high end of the range, because indoor air tends to be cleaner than industrial workplace air that would be targeted for monitoring.

Human exposure studies generally focus on respirable particles rather than total SPM. A cyclone or a virtual

a Based on Lioy and Lioy.19)
impactor can be used to limit the size of particles allowed into the sampler. Typical particle-size cuts are 10 µm or smaller and 2.5 µm or smaller.\(^{(8)}\)

If the species of interest include VOCs and SVOCs that exist in both gaseous and particle-bound states in air, the sampler may consist of a filter to collect particles followed by a sorbent to collect gaseous species. The filter–sorbent approach works well for measuring total concentrations of such species in air, but it does not allow accurate, separate measurements of gaseous and particle-bound concentrations. During sampling, gaseous semivolatiles from sampled air may be adsorbed by particles already collected on the filter, and particle-bound semivolatiles collected on the filter may be volatilized into the sampled air and swept on to the sorbent. Thus, the particles on the filter may become enriched with some species and depleted of others during sampling.

An approach has been developed for sampling ambient (or outdoor) air that allows separate measurements of gaseous and particle-bound concentrations of semivolatiles. The approach takes advantage of the vast difference in size (actually mass) between molecules and particles. Molecules in air move at speeds that are orders of magnitude faster than even small particles. As a result, molecules diffuse much faster than particles. A diffusion denuder is designed to take advantage of this difference in rates of diffusion to remove organic molecules (but not particles) from sampled air before the air (and particles) reach the filter.\(^{(22)}\) A diffusion denuder is an array (usually either a honeycomb or annular configuration) of glass or fused-silica tubes that are coated on interior surfaces with a sorbent. The length of the denuder, the internal cross-sectional area of openings through the denuder, and the flow rate of sampled air determine the residence time of sampled gas within the denuder. The dimensions of the denuder and the sampling flow rate are adjusted to values that allow sufficient residence time within the denuder for gaseous molecules, but not particles, to diffuse to the walls of the denuder, where they are trapped by the sorbent. Particles pass through the denuder and collect on the filter. Target species that volatilize from the collected particles during sampling are collected on a bed of sorbent downstream from the filter. Thus, gaseous material from the sampled air is collected in the denuder, and particle-bound material, on the filter and the sorbent. The fractions are then desorbed and analyzed separately.

### 6.3 Analyzing Particles and Particle-bound Chemical Species

Typically, total suspended particle concentration is calculated as the mass of particles collected divided by the volume of gas sampled. The same term generally applies to samples collected with or without a particle-size selection device in the sampling system. The particle-size cut points most often used are 10 µm, which allow collection of particles (or particulate matter) with aerodynamic diameters of 10 µm or less (PM\(_{10}\)), and 2.5 µm, which allows collection of particles with aerodynamic diameters of 2.5 µm or less (PM\(_{2.5}\)). The former (PM\(_{10}\)) particles are small enough to be inhaled into the lungs, and the latter (PM\(_{2.5}\)) are small enough to be inhaled into the smallest passageways within the lungs. Obviously, PM\(_{2.5}\) is a subset of PM\(_{10}\), but PM\(_{2.5}\) also represents the most deeply inhaled particles.

If chemical species associated with collected particulate matter are being measured, the filter, the sorbent, and the denuder, if used, are solvent-desorbed and analyzed according to procedures for organic and inorganic species described elsewhere.

### 6.4 Particles of Particular Concern

Particles that deliver extremely hazardous or carcinogenic species directly to the lungs over extended periods of time represent a serious threat to human health. Several sources of particles that are found in indoor air and that carry known or suspected carcinogens are discussed below.

#### 6.4.1 Environmental Tobacco Smoke

ETS is a complex mixture of volatile, semivolatile, nonvolatile, and particulate matter that may contain more than 3800 chemical species, including heavy metals. Many of the organic and inorganic species discussed above are present in tobacco smoke. The composition and distribution of the components of ETS change continuously as compounds are adsorbed on to or desorbed from particles and as the more reactive compounds are converted into other species.

Because of the complexity of the mixture and the fact that some of the compounds in ETS also come from other sources, exposure to ETS is quite difficult to measure directly. Typically, respirable suspended particle concentration or the concentration of nicotine (CAS 54-11-5),\(^{(8)}\) an organic compound that is specific to ETS, is measured by procedures described in previous sections for particles and organic compounds.

Yet another way to assess exposure to ETS is through analysis of physiological fluids of exposed persons. In this case, exposed persons have become the collection medium. The presence of nicotine or its major metabolite, cotinine, in saliva, blood, or urine is entirely due to exposure to tobacco, tobacco smoke, or ETS. The measurement of nicotine and cotinine in physiological fluids of active smokers or persons exposed to ETS...
(sometimes called passive smokers because they are exposed to ETS but do not smoke themselves) is generally accomplished by GC with a nitrogen-sensitive detector. The GC method can be used to measure nicotine concentrations as low as 1 ng mL\(^{-1}\) of fluid and concentrations of cotinine as low as 6 ng mL\(^{-1}\).

**6.4.2 Particles from Cooking and Heating Activities**

Soot particles from poorly vented heaters and oily mist and smoke from cooking can contain PAHs and other carcinogens. As described in the organic compounds section, PAHs are present in both particle-bound and gaseous states. The particles are collected as described above, and the PAHs are solvent-desorbed from the collection media and are typically measured by GC with an appropriate detector.

**6.4.3 Other Respirable Particles**

Any kind of respirable particle, whatever the source, has the potential to introduce carcinogens or other harmful species directly to the lungs and bloodstream of exposed persons.

**7 REMARKS**

Monitoring of carcinogens in indoor air is obviously not a simple task. The methods described here have, for the most part, been thoroughly evaluated by many different laboratories. A steady stream of newer, more sensitive techniques and instruments is appearing in the environmental literature and in the marketplace.

As an example, a recent journal article reported the measurement, by an automated analysis, of 1 pg of a VOC, which corresponds to less than 1 part per trillion of the compound in a 1-L air sample.\(^{23}\) Such a feat would have been impossible only a few years ago. Unfortunately, so-called allowable concentrations of some toxic and carcinogenic species are still defined by the sensitivity limitations of the methods available to measure them rather than by the risk those species pose to human health.

Charged particle activation analysis (CPAA) is an analytical method for elemental analysis. It is based on charged particle (CP) induced nuclear reactions producing radionuclides, that are identified and quantified by their characteristic decay radiation. CPAA allows trace element determination in the bulk of a solid sample, as well as characterization of a thin surface layer, i.e. determination of mass thickness or composition.

Advantages of CPAA are: (1) good precision, (2) low detection limit, (3) outstanding accuracy, (4) absolute, i.e. reference method, (5) independent, i.e. based on a totally different principle than more common methods for elemental analysis (atomic/optical emission and mass spectrometry), and hence not subject to the same systematic errors, (6) traceability, (7) not subject to surface contamination for trace element determination in the bulk, (8) if instrumental analysis is not possible it is not subject to reagent blank errors, and (9) errors due to nonquantitative yield (and even nonreproducible yield) can be corrected for. Disadvantages of CPAA are its inherent complexity and costs, it is not suitable for liquid samples, and heating occurs during irradiation. Speciation, depth profiling, or scanning is not possible.

This article covers (1) the principles on the slowing down of CPs in matter, nuclear reactions, and interferences; (2) experimental details concerning irradiation and activity measurement; (3) conceptual and experimental procedures and data handling, from the problem to the final result; (4) perspectives. References to relevant databases are
made. A systematic overview of all possible CPAA applications is beyond the scope of this article.

1 INTRODUCTION

CPAA is an analytical method for elemental analysis. Specialization (i.e., discrimination between different oxidation states of the analyte element or between different compounds) is not possible. CPAA is based on CP induced nuclear reactions producing radionuclides and their characteristic decay radiation is measured. The radionuclide is identified by measuring its energy and/or half-life, i.e., qualitative analysis. Quantitative analysis is performed by measuring the number of particles or photons emitted, i.e., radioactivity.

CPAA provides a good precision, low detection limits, and accuracy. It can be considered as an absolute (reference) and an independent method for elemental analysis of solid samples. There is no need for standards that are comparable to the samples, or for standards where the analyte content is determined by another analytical method. Traceability conditions are fulfilled, except for the stopping power correction. CPAA is based on a totally different principle than more common methods for elemental analysis (e.g., atomic or optical emission and mass spectrometry), and hence is not subject to the same systematic errors. It is not subjected at all to errors related to dissolution of the sample and chemical separation (e.g., preconcentration). If instrumental analysis is not possible, then radiochemical CPAA can be applied. Errors due to reagent blanks do not exist. Errors due to surface contamination (e.g., determination of bulk oxygen in aluminum) can be avoided easily. Finally, errors due to nonquantitative yield, and even nonreproducible yield, can be corrected for.

CPAA can be applied for trace element determinations as well as for characterization of thin surface layers. It has proven its outstanding capabilities for the determination of trace light elements (boron, carbon, nitrogen, and oxygen) in the bulk of high purity metals and semiconductors. Recently, CPAA has been applied for the characterization of surface layers, such as the determination of mass thickness or composition (stoichiometry). The disadvantages of CPAA are its inherent complexity and cost, it is not suitable for liquid samples, and heating occurs during irradiation. Neither depth profiling nor scanning is possible for surface characterization.

2 INTERACTION OF CHARGED PARTICLES WITH MATTER

Most CPs do not induce nuclear reactions and are slowed down in matter. The energy loss is described by the stopping power, and the penetration depth in matter by the range.

2.1 Stopping Power

The stopping power of a target for a CP is the energy loss of the CP for an amount of target atoms. In CPAA it is most convenient to use mass stopping power, i.e., the energy loss per unit mass thickness, as given in Equation (1).

\[
S = \frac{-dE}{dx} \tag{1}
\]

where \(S\) is the mass stopping power, in \(\text{MeV g}^{-1} \text{cm}^2\); \(E\) is the energy, in \(\text{MeV}\); and \(x = \rho l\), the mass thickness, in \(\text{g cm}^{-2}\) (\(\rho = \text{mass density in g cm}^{-3}\) and \(l = \text{thickness in cm}\)).

The stopping power is determined by the nature of the CP, energy of the CP, and nature of the target, as given in Equation (2).

\[
S_a = Z_a^2 S_p \left( \frac{E_a}{A_a} \right) \tag{2}
\]

where \(Z_a\) is the atomic number and \(A_a\) is the mass number. The subscripts “a” and “p” refer to a CP and proton, respectively.

For the energy range of interest in CPAA (\(\geq 1\text{ MeV}\)) and Equation (2) show that the stopping power for 20-MeV deuterons is equal to the one for 10-MeV protons, and the stopping power for 30-MeV helium-3 particles and 40-MeV alpha particles is four times that of 10-MeV protons. The stopping power decreases with the CP energy (\(\sim 1/E\)) (Figure 1b) and for increasing atomic number of the target (Figure 1c). This decrease is steep for low-Z targets.

Stopping power data for elemental matter can be calculated based on the Bethe formula. For mixtures, the additivity rule of Bragg and Kleeman (Equation 3) is applied.

\[
S = \sum_{i=1}^{n} w_i S_i \tag{3}
\]

where \(w_i\) is the mass fraction of the \(i\)th component, \(S_i\) is the mass stopping power of the \(i\)th component, and \(n\) is the number of components. For compounds, deviations from the Bragg rule may occur due to chemical binding effects. For the energy range of interest in CPAA (\(\geq 1\text{ MeV}\)) these deviations can be neglected.

2.2 Range

As a consequence of the stopping power phenomenon, CPs lose their energy and are stopped at a depth called the “range”. From Equation (1) the mass range, \(R\), for a
CHARGED PARTICLE ACTIVATION ANALYSIS

Figure 1(a) and Equation (5) show that the range of 20-MeV deuterons is twice that of 10-MeV protons, the range of 30-MeV helium-3 particles is 75% that of 10-MeV protons, and the range of 40-MeV $\alpha$-particles is equal to that of 10-MeV protons. The range increases with the CP energy ($\sim E^2$) (Figure 1b) and for increasing atomic number of the target (Figure 1c). The increase is steep for low-Z targets.

For CPAA the CP interaction with matter can be described simply: CPs traverse the target undeflected (i.e. nearly straight lines), the beam intensity (the number of CPs per unit time) is almost unchanged, and all CPs are stopped at the same depth in the target (at the range). Consequently, linear versus projected range, and range straggling, should not be considered for CPAA.

2.3 Stopping Power and Range Data

Stopping power and range data can be obtained from the SRIM (Stopping and Range of Ions in Matter) PC software package of Ziegler, IBM Research. The principles are described by Ziegler et al. To calculate ranges expressed in length (as in SRIM) the mass density is required. For mixtures and compounds (not listed in the compound dictionary) the mass density should be introduced, by the user, into the SRIM package. (An updated review of Nuclear Data for Charged Particle Activation is available at http://allserv.rug.ac.be/~kstrykmen/nuclear.)

3 CHARGED PARTICLE INDUCED NUCLEAR REACTIONS

CPAA is based on a nuclear reaction $A + a \rightarrow B + b + Q$, or $A(a,b)B$, where $A$ is the stable target nuclide (at rest), “$a$” is a CP (accelerated), $B$ is a radionuclide, “$b$” is the particle(s) or photon emitted, and $Q$ is the $Q$-value. Two important characteristics are the minimum CP energy required to induce such a nuclear reaction, and the probability that this reaction will proceed. As CPs are slowed down when traversing matter, as described in section 2, the latter characteristic should be known as a function of the CP energy.

3.1 $Q$-value and Threshold Energy

The $Q$-value is the energy released by one single nuclear reaction. It is related to the difference between the resting masses of reactants and products, as given in Equation (6).

$$ Q = (m_A + m_a - m_B - m_b)c^2 $$     (6)

where $m$ is the nuclidic mass and $c$ is the velocity of light. Nuclidic masses can be replaced by atomic masses,
as electron masses are cancelled, at least if this also is done for “a” and “b” (e.g. for a (p,α) reaction the atomic masses of $^1\text{H}$ and $^4\text{He}$, respectively, are used). A nuclear reaction can be endoergic ($Q < 0$) or exoergic ($Q > 0$). To induce endoergic reactions the CPs should have a minimum energy, i.e. the threshold energy $E_t$, which is slightly higher than $\pm Q$. The compound nucleus, formed by collision of the CP “a” and the target nucleus $A$, retains a fraction of the kinetic energy of the CP, i.e. $m_a/(m_A + m_a)$. This fraction is “lost” to compensate for the shortfall of mass or energy for an endoergic reaction. Approximating the nuclidic mass by the mass number $A$ for the recoil energy correction, the threshold energy is given by Equation (7).

$$E_t = -\frac{A_A + A_a}{A_A} Q \quad \text{for } Q < 0$$

$$E_t = 0 \quad \text{for } Q \geq 0 \quad (7)$$

where $E_t$ is the threshold energy. For exoergic nuclear reactions the threshold energy is zero by definition. $Q$-values and threshold energies can be calculated from the Audi and Wapstra “adopted masses” 1993(3) or 1995(4) with the on-line program Q-calc, at the Lund Nuclear Data WWW Service (Lund University, Sweden), at the National Nuclear Data Center (NNDC, Brookhaven National Laboratory, USA), and at the International Atomic Energy Agency (IAEA, Austria),(5) or as a Fortran-77 program(6) for a VAX-VMS system.

### 3.2 Coulomb Barrier

The Coulomb barrier also determines the minimum CP energy needed to induce a nuclear reaction. The coulombic repulsive force between the target nucleus and the CP dominates at “large” distances, and increases when the CP approaches the target nucleus. At some particular distance (i.e. the sum of the radii of CP and target nucleus) the attractive nuclear force balances the Coulomb repulsive force. The decrease in the CP kinetic energy is given by the Coulomb barrier, as in Equation (8).

$$E_C \approx \frac{A_A + A_a}{A_A} \frac{Z_A Z_a}{\sqrt{A_A} + \sqrt{A_a}} \quad (8)$$

where $E_C$ is the Coulomb barrier, in MeV; and $\sqrt{A}$ is proportional to the nucleus radius. The Coulomb barrier for $^3\text{He}$ and $^4\text{He}$ particles is about twice as high as that for protons or deuterons, and it increases with the atomic number of the target nucleus, roughly $Z_A^2$, as shown in Figure 2.

The kinetic energy – the CP lost by the Coulomb barrier – is released again when a nuclear reaction occurs. Consequently, the Coulomb barrier influences the energetics of a nuclear reaction only in that a CP must have a kinetic energy higher than the Coulomb barrier before the reaction can occur. Quantum mechanical treatment of the problem explains that the reaction probability (see section 3.3) for CPs with a kinetic energy lower than the Coulomb barrier is not exactly zero, but very low, and rapidly drops as the CP energy decreases.

### 3.3 Nuclear Reaction Cross-section

The probability of a nuclear reaction is expressed as the (nuclear reaction) cross-section, which has the dimensions of area. This originates from the simple picture that the probability for a reaction between the target nucleus and the incident CP is proportional to the geometric cross-section that the target nucleus presents to a beam of CPs. The average cross-section is somewhat near $10^{-28} \text{ m}^2$. The barn (1 b = $10^{-28} \text{ m}^2$) is used as a unit for nuclear reaction cross-section.

The cross-section for a particular reaction (also called the partial reaction cross-section) depends on the energy of the CP. It is zero for CPs below the threshold energy of that reaction. If the Coulomb barrier is higher than the threshold energy (i.e. always the case for exoergic reaction, as $E_t = 0$ for $Q > 0$), then the cross-section is very low in the energy interval between the threshold energy and the Coulomb barrier. For CP energies exceeding the threshold energy and Coulomb barrier, the cross-section increases up to a maximum (typically 1 b), and decreases as more complex reactions become competitive. Two annotated examples are given in Figure 3(a) and (b).

### 3.4 Cross-section Data: Excitation Function and Activation Curve

As CPs are slowed down in matter, knowledge of the cross-section as a function of the energy is required.
CHARGED PARTICLE ACTIVATION ANALYSIS

for CPAA. However, absolute data are not required (sections 5.2 and 5.3). Therefore the excitement function (or curve) indicates the absolute cross-section as a function of the energy, while the activation curve indicates a relative data set.

Experimental excitation functions can be obtained from the EXFOR (or CSISRS) database at NNDC mirrored at IAEA and the Nuclear Energy Agency (NEA), France. The data sets in Figure 3(a), obtained from this database, the agreement is fairly good, but this is not representative for the vast majority of CP induced reactions. Actually the $^{14}$N(d,n)$^{15}$O reaction has been studied in great detail, because it is extremely important for positron emission tomography (PET), an imaging technique for quantifying the oxygen metabolism, blood flow and blood volume in nuclear medicine.

If no experimental data are available, excitation functions can be estimated using the very simple equations and data from Keller et al.(8)

The experimental procedure needed to obtain an activation curve is quite simple if the target element (A) is available as “thin” foil. “Thin” means much smaller than the range. A stack of “thin” foils (total thickness ≥ range) is irradiated, and the foils are measured individually. After decay correction the count rate measured is proportional to the cross-section, as will be shown in Equation (17). Excitation function data require absolute activity measurements, absolute beam intensity monitoring, and absolute energy measurement of the incident CP beam. However, an activation curve (relative cross-section data) is sufficient for CPAA.

In contrast to neutron induced reactions, no experimental data are available for most of the CP induced reactions. Additionally, if different data sets are available, their agreement is often unsatisfactory. Therefore approximate methods for standardization have been developed in CPAA.

3.5 Radionuclides Formed by Charged Particle Induced Reactions

Which radionuclides are formed by irradiation of a particular matrix by a CP with a particular energy, and what is their approximate activity level?

The first question can be answered by observing a chart of nuclides. This represents all nuclides with relevant data for CPAA as chemical symbol, mass number, isotopic abundance (stable nuclides), half-life, decay mode, and decay energies (radionuclides). For proton irradiation, for example, the reaction types given in Figure 4 should be applied to all stable isotopes of all elemental components of the matrix. In the inventory of possible nuclear reactions two categories can be rejected: those leading to stable nuclides, and those with a threshold energy higher than the CP energy. Reactions for which the Coulomb barrier is higher than the CP energy induce only low activity levels, but cannot be excluded. An annotated example is given in Figure 4 for a 10-MeV proton irradiation of nitrogen.

The induced activity is proportional to the number of CPs per time unit, irradiation time (not linearly), number of target nuclides, and reaction cross-section. The number of target nuclides is inversely proportional to the relative atomic mass of the element, and proportional to the mass fraction of the element in the target, the isotopic abundance of the target nuclide, and the activated depth, i.e. the range of the target at the incident energy minus

Figure 3 Excitation functions. (a) The $^{14}$N(d,n)$^{15}$O reaction is exoergic ($Q > 0$), consequently its threshold energy is zero. Below the Coulomb barrier (2.2 MeV) the cross-section is low, but not zero. It increases steeply around the Coulomb barrier energy. (b) The $^{56}$Fe(p,n)$^{56}$Co reaction is endoergic ($Q = -5.3$ MeV), hence its threshold energy equals 5.4 MeV. The cross-section is zero below 5.4 MeV, increases to a maximum at 12–13 MeV, and decreases at higher energies, as the $^{56}$Fe(p,2n)$^{55}$Co reaction ($E_t = 15.7$ MeV) becomes competitive. For the (p,2n) reaction the reaction cross-section also increases up to a maximum at 27–30 MeV, and decreases at higher energies, as the $^{56}$Fe(p,3n)$^{54}$Co reaction ($E_t = 30.1$ MeV) becomes competitive. For thick target yield (TTY), see section 3.5.
NUCLEAR METHODS

4 INTERFERENCES

The determination of an analyte element is based on the reaction $A(a,b)B$, where $A$ is a stable nuclide of that analyte element and $B$ is a radionuclide (section 3). Three different types of interference can be distinguished: nuclear, spectral, and matrix.

4.1 Nuclear Interference

A radionuclide $B$ is also formed from an element other than the analyte element by a nuclear reaction $C(c,d)B$. $C$ is a stable nuclide of the interfering element.

$$t_w = \text{waiting time},$$
$$\overline{\sigma} = \text{average reaction cross-section, in mb (generally, 100 < \overline{\sigma} < 1000)},$$
$$R = \text{mass range, in g cm}^{-2} \text{ (section 2.2 and Figure 1)},$$
$$E_i = \text{incident energy},$$
$$E_{i/C} = \max(E_i, E_C) \text{ (sections 3.1 and 3.2)}.$$
The CP “c” is mostly identical to “a”, but nuclear interferences induced by secondary particles, e.g. fast or thermalized neutrons produced by (a,n) reactions, have to be considered also. Nuclear reactions can only be avoided by a proper choice of the CP energy if the threshold energy $E_t$ of the interfering reaction $C(c,d)B$ exceeds both the threshold energy and the Coulomb barrier of the analyte reaction $A(a,b)B$. To obtain high sensitivity, the CP energy is chosen at or just below the threshold energy of the interfering reaction.

Interference by the $^{14}\text{N}(d,t)^{15}\text{N}$ reaction (Figure 4b) could affect the determination of carbon by the $^{12}\text{C}(d,n)^{13}\text{N}$ reaction. As the threshold energy of the interfering reaction (4.9 MeV) exceeds that of the analyte reaction (0.3 MeV), as well as the Coulomb barrier (2.0 MeV), carbon can be determined sensitively and interference free by irradiation with 4.9-MeV deuterons. It is obvious that the difference in Coulomb barrier is largely insufficient to avoid nuclear interferences, and that the reaction $^{13}\text{C}(d,2n)^{13}\text{N}$ does not interfere with the determination of carbon.

### 4.2 Spectral Interference

A radionuclide D is formed by the nuclear reaction $C(c,d)D$ and the measurement does not resolve the activity of B and D. Spectral interferences can be avoided by:

1. The proper choice of the incident CP energy with respect to the threshold energy and the Coulomb barrier (analogous to nuclear interference).
2. Selective measurement of the radionuclide D with respect to radionuclide B by spectrometry or decay curve analysis (sections 7 and 9.2). The former is possible if the $\gamma$-lines differ by more than the energy resolution of the spectrometer used. The latter is possible if the half-lives of the radionuclides C and D are sufficiently different (about a factor of 2 for comparable activities). If D is short-lived, i.e. its half-life is ≥10 times lower as compared to B, then selective measurement (interference < 0.4%) is possible for an irradiation and waiting time equal to one half-life of B (for comparable relative atomic mass, mass fraction, isotopic abundance, cross-section, and range, Equation 9).
3. Radiochemical separation of B from D, if both are not radioisotopes, i.e. radionuclides of the same element (section 8.4).

Nitrogen can be determined by the $^{14}\text{N}(p,n)^{14}\text{O}$ as well as by the $^{14}\text{N}(p,\alpha)^{11}\text{C}$ reaction (Figure 4b). The former reaction leads to $^{14}\text{O}$, a $\beta^+$; $\gamma$-emitter. Measuring the 2313-keV $\gamma$-ray with a Hewlett-Packard Ge spectrometer, the former reaction only undergoes interference by other $\gamma$-emitters within the energy resolution (≈2 keV) of that spectrometer. There could be interference with the latter reaction by, for example, the $^{13}\text{C}(p,n)^{13}\text{N}$, $^{14}\text{N}(p,n)^{14}\text{O}$, $^{15}\text{N}(p,n)^{15}\text{O}$, and $^{16}\text{O}(p,\alpha)^{15}\text{N}$ reactions, all leading to $\beta^+$ (positron) emitters. Measurement of their annihilation radiation (section 7.1) is aspecific and thus could cause spectral interference. As the threshold energies (3–6 MeV) and the Coulomb barriers are not sufficiently different, the interference cannot be avoided by a proper choice of the proton energy. Measurement of the activity as a function of time followed by decay curve analysis (section 9.2) leads to the initial activity of each component if the activity levels are comparable within 1 to 3 orders of magnitude. It is obvious that the other reactions [(p,n), (p,\alpha)] on the analyte element (N) also cause spectral interference (in contrast to nuclear interference). Alternatively, $^{13}\text{C}$ can be radiochemically separated by combustion in oxygen and trapping of the carbon dioxide formed, as the other radionuclides are not radioisotopes of carbon. The latter is called radiochemical analysis (section 8.4) or determination, in contrast to instrumental analysis.

### 4.3 Matrix Interference

Matrix interference is a special case of spectral interference. As CPAA is primarily a method for trace element determinations or thin-layer characterization, the activity level of the main matrix components could be several orders of magnitude higher than the activity of the analyte element, e.g. $10^6$ for a trace element determination at the $\mu$g-g⁻¹ or ppm level. Then instrumental analysis is almost impossible, even for quite different $\gamma$-energies and/or half-lives. Instrumental analysis is only possible for a proper choice of the CP energy, as an alternative for a highly specific radiochemical separation. It is obvious that the determination of light elements (boron, carbon, nitrogen, oxygen) in a high-Z sample is favored by the Coulomb barrier (section 3.2).

### 5 STANDARDIZATION

Standardization or calibration in CPAA is performed in a relative way, i.e. a sample and a standard are both irradiated and measured. To preserve the advantage of CPAA as an “absolute” or “independent” method, there is no need for a standard similar to the sample and certified for the analyte concentration or mass thickness. The standard is pure elemental matter or a pure compound with exactly known stoichiometry (section 8.1). In a relative method there is no need for absolute data, and errors are cancelled.
For trace element determination in the bulk of a sample, the experimental data (activity) are related to the mass fraction (or concentration) expressed in, for example, mg kg$^{-1}$ (SI), mg g$^{-1}$, ppm (parts per million) or µg kg$^{-1}$, ng g$^{-1}$, ppb (parts per billion).

Surface characterization of thin layers stands for the determination of the partial mass thickness. For an Al$_2$O$_3$ layer the partial/total mass thickness is the amount of Al/Al$_2$O$_3$ per surface unit, expressed in µg cm$^{-2}$. From the partial mass thickness the total mass thickness, or thickness or composition (mass fraction or stoichiometry), can be calculated (section 10). As standardization for trace element determinations in the bulk of a sample and surface characterization have a common and a specific part, the following is divided into three sections. The word “target” will be replaced by “sample” or “standard” in sections 5.2 and 5.3.

5.1 General

The number of radionuclides produced per unit time by irradiation of an infinitesimally thin target is determined by the balance of the increase due to nuclear reactions (proportional to the number of CPs per time unit (i.e. beam intensity, the cross-section and the number of target nuclides per surface unit) and the decrease due to radioactive decay ($-\lambda N$) (Equation 10).

$$\frac{dN}{dt} = I\sigma n dl - \lambda N$$  \hspace{1cm} (10)

where

$N$ = number of radionuclides,
$t$ = time,
$I$ = number of CPs per unit time or beam intensity,
$\sigma$ = partial nuclear reaction cross-section,
$n$ = number of target nuclides per unit volume,
$l$ = thickness of the target,
$\lambda$ = $\ln(2)/t_{1/2}$, decay constant of the radionuclide formed (where $t_{1/2} =$ half-life).

From Equation (10), the number of radionuclides formed and the induced activity after an irradiation time $t_i$ can be calculated. On condition that the beam intensity is constant, this yields Equation (11).

$$A = \lambda N = Iw \frac{1}{M} N_A \theta \left(1 - e^{-\lambda t_i}\right) \sigma dx$$  \hspace{1cm} (11)

where

$A$ = activity in Bq,
$w$ = mass fraction of the activated element in the target,
$M$ = molar mass of the activated element,
$N_A$ = Avogadro’s constant,
$\theta$ = isotopic abundance of the target nuclide,
$t_i$ = irradiation time.

A CP beam is stopped completely in a “thick” target, in which the mass thickness $D$ is at least equal to the range $R$. To calculate the activity for such a “thick” target one has to integrate $\sigma dx$ in Equation (11), using the stopping power (Equation 1), as the cross-section has to be expressed as a function of the energy. The calculation is given by Equation (12).

$$\int_{0}^{R} \sigma dx = \int_{E_i}^{E_0} \frac{\sigma dE}{E} = \frac{E_i}{E_0} \sigma \frac{dE}{dx} \approx \frac{E_i}{E_0} \frac{dE}{dx}$$  \hspace{1cm} (12)

where $R$ is the mass range of the CP in the target, in g cm$^{-2}$; $E_i$ is the incident CP energy, in MeV; $E_0$ is the threshold energy, in MeV; and $S$ is the mass stopping power, in MeV g$^{-1}$ cm$^2$. The integration limit $E = 0$ (corresponding to $x = R$) may be replaced by the threshold energy $E_i$, as the cross-section is zero for $E < E_i$.

If the excitation function is not known, an energy $E_{i/c}$ can be defined as the maximum of threshold energy and Coulomb barrier. The cross-section can be supposed to be zero below $E_{i/c}$, while above $E_{i/c}$ it is constant. The following approximation (Equation 13) is obtained from Equations (2) (range definition) and (12).

$$\int_{0}^{R} \sigma dx = \int_{E_i}^{E_{i/c}} \frac{\sigma dE}{E} \approx \frac{E_i}{E_{i/c}} \frac{dE}{dx}$$  \hspace{1cm} (13)

if $\sigma(E) = 0$ for $0 \leq E \leq E_{i/c}$; and $\sigma(E) = \bar{\sigma}$ for $E_{i/c} \leq E \leq E_i$; where $\bar{\sigma}$ = average cross-section, and $E_{i/c} = max(E_i, E_C)$.

From Equations (11), (12), and (13) the activity induced in a thick target (i.e. TTY) is given by Equation (14), which approximates to Equation (15).

$$A = Iw \frac{1}{M} N_A \theta \left(1 - e^{-\lambda t_i}\right) \bar{\sigma}$$  \hspace{1cm} (14)

$$A \approx Iw \frac{1}{M} N_A \theta \left(1 - e^{-\lambda t_i}\right) \bar{\sigma} (R_{E_i} - R_{E_{i/c}})$$  \hspace{1cm} (15)

The target is assumed to be homogeneous, and the decrease in beam intensity (due to nuclear reactions) is negligible. Consequently, neither $w$ nor $I$ is a function of $x$ or $E$.

For a “thin” target, i.e. a target that nearly reduces the CP energy, where the mass thickness $D$ is much lower than the mass range $R$, the induced activity is given by Equation (16), which approximates to Equation (17).

$$A = Iw \frac{1}{M} N_A \theta \left(1 - e^{-\lambda t_i}\right) \frac{E_i}{E_0} \frac{dE}{dx}$$  \hspace{1cm} (16)

$$A \approx Iw \frac{1}{M} N_A \theta \left(1 - e^{-\lambda t_i}\right) \sigma_0 D$$  \hspace{1cm} (17)
where $E_o \approx E_i$, the outgoing energy, in MeV; $\sigma_0$ is the cross-section for $E_o < E < E_i$; and $D \ll R$, the mass thickness of the “thin” target, in g cm$^{-2}$.

5.2 Trace Element Determination in the Bulk of a Sample

A relative method is applied, whereby a “thick” sample and a “thick” standard are irradiated and measured separately. As the nature of sample and standard is different, a correction, $F$, has to be made owing to the different stopping power (or range) of sample versus standard. Applying Equations (14) and (15) for, respectively, a sample “x” and a standard “s”, and assuming the sample and standard to have equal natural abundance, the mass fraction of the analyte in the sample yields Equation (18), in which $F$ is given by Equation (19), which approximates to Equation (20). (To comply with SI the “mass fraction” $w$ is used, while in the CPAA literature often “concentration” $c$ is used.)

$$w_x = w_s \frac{A_x I_x (1 - e^{-\lambda_x})}{A_s I_s (1 - e^{-\lambda_s})} F$$  \hspace{1cm} (18)

where the subscripts x and s refer to a “thick” sample, and a “thick” standard, respectively.

$$F = \frac{E_x \sigma dE}{E_s \sigma dE} \frac{S_s}{S_x}$$ \hspace{1cm} (19)

$$F \approx \frac{(R_{E_i} - R_{E_{i+1}})_x}{(R_{E_i} - R_{E_{i+1}})_s}$$ \hspace{1cm} (20)

The mass fraction (concentration) of the analyte in the sample $w_x$ can be calculated from:

- the mass fraction of the analyte element in the standard $w_s$,
- the ratio of the activity in sample and standard at the end of irradiation $A_x/A_s$,
- the ratio of the beam intensity for standard and sample $I_s/I_x$,
- the decay constant of the radionuclide formed $\lambda$,
- the F-factor, i.e. a correction for different stopping power of sample versus standard.

The F-factor can be calculated exactly by Equation (19), requiring:

- relative cross-section data $\sigma$ from the threshold energy $E_i$ up to the incident energy $E_i$,
- relative stopping power data for standard and sample $S_s, S_x$ in the same energy interval.

If no cross-section data are available, the F-factor can be approximated by Equation (20). This approximation yields quite good results if one or more of the following conditions (in decreasing order of importance) are fulfilled:

- the atomic number of sample and standard are similar,
- the threshold energy or the Coulomb barrier for the nuclear reaction is high,
- the incident energy is high.

The “atomic number” of a compound is, in principle, that of the element with the same stopping power. Practically, the atomic numbers of the elemental components can be averaged: mass fraction weighed. For simplicity Equation (13) was derived supposing a “step-wise” excitation function, which does not agree with reality. A detailed study showed that this approximation can also be obtained by assuming that $S_s/S_x$ is a constant as a function of the energy. If the above mentioned conditions are fulfilled, the latter assumption holds better, as can be observed from the parallel lines in Figure 1(b).

Several approximate methods, not requiring cross-section data, have been proposed and evaluated. The second method of Ricci and Hahn (19) is known as the first method of Ricci and Hahn. The second method of Ricci and Hahn (20) is fundamentally false. The method of Chaudri et al. (21) yields nearly the same approximation as the first method of Ricci and Hahn. Chaudri’s method makes use of stopping power data instead of range data, as shown in Equation (21).

$$F \approx \frac{(S_{E_m})_x}{(S_{E_m})_s}$$ \hspace{1cm} (21)

where $E_M = (E_i + E_{i+1})/2$. The “average stopping power method” is an outstanding approximate method with a negligible error that can be calculated. However it needs cross-section data, and therefore there is no reason to prefer it to Equation (19). The method has more intellectual than practical merits.

The internal standardization method, not requiring stopping power data for the sample, has more practical applications. The major composition of a sample is often not known, or the composition changes during irradiation. Samples can lose their organic fraction due to heating, and consequently positive errors are made because the stopping power of hydrogen is 3–5 times higher than for the other elements (Figure 1c). Also, approximate methods not requiring cross-section data have been proposed.

The “two reactions method” does not require stopping power data. Its main advantage is that accuracy of the...
method is not influenced by the accuracy of the stopping power data. Experimentally, the method is quite complex.

Also, the standard addition method does not require stopping power data.\textsuperscript{(26,27)} As CPAA is mainly intended for solid samples, the applicability of this method is limited to powdered samples.

A critical review is given by Strijckmans.\textsuperscript{(28)}

### 5.3 Surface Characterization of Thin Layers

As for trace element determinations, a relative method is also applied. A “thin” surface layer is irradiated and measured together with a “thin” or “thick” standard. From Equations (16) and (17) the partial mass thickness, using a “thin” standard, yields Equation (22), which approximates to Equation (23).

\[
w_x D_x = w_x \frac{A_x I_x (1 - e^{-l x})}{A_x I_x (1 - e^{-l x})} \frac{E_i}{S} \sigma_0 \frac{dE}{E_i} \tag{22}
\]

where \( wD \) is the partial mass thickness; \( D \ll R \), the total mass thickness; and the subscripts \( x \) and \( s \) refer to a “thin” surface layer and a “thick” standard, respectively.

For a “thin” surface layer (order of magnitude \( \mu \) to nm) the approximation made in Equation (17) holds. For the “thin” standard (order of magnitude 10 to 100 nm) one has to check if the cross-section is still constant in the energy interval \( E_{ox} - E_i \). Although Equation (23) does not contain cross-section data, a knowledge of such data, at least relatively in the above mentioned interval, is required in order to evaluate the equation’s applicability.

If thin standards are not available, analogous formulae can be obtained from Equations (14), (15), and (17) for a “thick” standard. The partial mass thickness using a “thick” standard yields Equation (24), which approximates to Equation (25).

\[
w_x D_x = w_x \frac{A_x I_x (1 - e^{-l x})}{A_x I_x (1 - e^{-l x})} \frac{E_i}{S} \sigma_0 \frac{dE}{E_i} \tag{24}
\]

\[
w_x D_x \approx w_x \frac{A_x I_x (1 - e^{-l x})}{A_x I_x (1 - e^{-l x})} \frac{E_i}{S} \sigma_0 (R_{E_i} - R_{E_i/c}) \tag{25}
\]

where the subscripts \( x \) and \( s \) refer to a “thin” surface layer and a “thick” standard, respectively. Equation (24) requires at least relative cross-section data. From Equation (25) no approximation can be written that does not require cross-section data. The average cross-section in the energy interval \( E_{i/e} \) to \( E_i \) is never comparable to the cross-section at the incident energy (actually in the very narrow interval \( E_o \) to \( E_i \)). For trace element analysis in the bulk of a sample such an approximation was possible (section 5.2, and Equations 18 and 20), and it results in accurate analyses observing the conditions mentioned in section 5.2.

### 5.4 Conclusions

The standardization formulae to be used are summarized in Table 1. For trace element determinations in the bulk of a sample (mass fraction), accurate results can be obtained without a knowledge of cross-section data if one or more of the conditions are fulfilled. For surface characterization (mass thickness determination) accurate results can also be obtained without a knowledge of cross-section data if a “very thin” standard is used.

### 6 CHARGED PARTICLE IRRADIATION

#### 6.1 Accelerator

CPs have to be accelerated to an energy higher than the Coulomb barrier and lower than the threshold energy of reactions that are more complex than \((a,n)\) and \((a,\alpha)\). The lower limit is to obtain high reaction cross-sections, and consequently high sensitivity; the upper limit is to avoid nuclear interferences by these complex reactions. For protons and deuterons the ideal energy range should be 5–25 MeV, while for helium-3 and \(\alpha\)-particles it should be twice as high. A cyclotron is an ideal accelerator for this energy range, although a tandem Van de Graaff also covers the lower energy range.\textsuperscript{(29)}

A tandem Van de Graaff is a DC linear accelerator, the DC source being an electrostatic Van de Graaff generator. The tandem principle is related to the use of the same voltage to accelerate the particles (e.g. protons) twice. First, negative hydrogen ions (H\textsuperscript{+}) are accelerated to
5 MeV by applying 5 MV from the electrostatic generator; then the ion is stripped from its electrons, and the same reversed voltage is applied again to accelerate to 10 MeV.

The tandem principle is applied a thousand-fold in AC accelerators. A cyclotron is an AC circular accelerator. A high-frequency electric field accelerates the CPs, following a spiral path, due to the magnetic field applied. Ideally, an isochronous cyclotron should be a multi-particle and variable energy accelerator. This implies that the magnetic field and the high-frequency electric field can be tuned, and that the magnetic field as a function of the radius can be adjusted (to compensate for relativistic mass increase during acceleration). Typically, an isochronous cyclotron has radial or spiral sectors in the magnet poles, a prerequisite for beam focusing. Cyclotrons that accelerate helium-3 particles should be equipped with a recuperation system. Typically, the energy can be tuned by a factor of 5–10.

However, the vast majority of cyclotrons in the world is the two-particle and fixed energy type, the so-called “baby cyclotron”. Their high-frequency electric and magnetic fields are fixed, and the magnetic field increases with the radius by the shape of the magnet poles. Protons or deuterons can be accelerated, the deuteron energy being half the proton energy. Such cyclotrons are negative-ion machines (H\(^+\) ions are accelerated, stripped, and the protons formed leave the magnetic field). Extraction of negative ions with a stripping foil is technically very simple compared to extraction of positive ions. These are extracted with a deflector: a strong DC electric field “extracts” the accelerated beam out of the magnetic field. The stripping foil (in contrast to a deflector) can be moved into the cyclotron, extracting a lower energy beam. Energy tuning of up to a factor of 2 is possible. Baby cyclotrons are widely used in nuclear medicine departments for PET, i.e. a functional imaging technique using biologically active molecules labeled with cyclotron-produced, short-lived positron emitters.

The beam requirements are not very severe. The energy should be well-defined (within 0.1 MeV is largely sufficient) to control interferences by their threshold energy and/or Coulomb barrier. The beam energy should be reproducible within several days, because this influences slightly the sensitivity. The beam intensity should be tunable from 0.01 to 5 \(\mu\)A, which is largely under the upper limit of these accelerators, and kept constant during irradiation (Equation 11 was calculated assuming that the beam intensity is constant). The unfavorable beam characteristics of a cyclotron versus a Van de Graaff accelerator, such as pulsed beam and energy resolution, are of no importance in CPAA.

### 6.2 Heat Release in a Target

CP irradiation can cause substantial heating to the sample. Indeed, standards can be irradiated for shorter times and/or at lower beam intensity. The heat release (power) in a “thick” target is given by the energy of one single CP multiplied by the number of CPs per unit time (Equation 26).

\[
Q = E \frac{I}{Z_a e} \tag{26}
\]

where
- \(Q\) = heat release (power), in W;
- \(E\) = CP energy, in J;
- \(I\) = beam intensity, in \(\mu\)A;
- \(Z_a\) = atomic number of the CP;
- \(e \approx 1.6 \times 10^{-19}\) C (the elementary charge);

or more practically, according to Equation (27),

\[
Q = \frac{E I}{Z_a} \tag{27}
\]

where
- \(Q\) is the heat release (power), in W; \(E\) is the CP energy, in MeV; and \(I\) is the beam intensity, in \(\mu\)A. For a “thin” target \(E\) should be replaced by the energy decrease for the CP traversing the sample, which can be written as the mass thickness of the target and its stopping power (Equation 28).

\[
Q = \frac{(E_i - E_o) I}{Z_a} = \frac{SD}{Z_a} \tag{28}
\]

where \(E_i\) is the incident energy, in MeV; \(E_o\) is the outgoing energy, in MeV; \(S\) is the mass stopping power, in MeV g\(^{-1}\) cm\(^2\); \(D\) is the mass thickness of the “thin” target, in g cm\(^{-2}\).

Heat is not released uniformly in the sample. It is obvious that the volume is determined by the irradiation surface and the CP range in the target. The depth distribution is given by the stopping power, as shown in Figure 5 for 10-MeV protons in a “thick” aluminum target. One can observe the Bragg peak at the very low energy side, i.e. for a depth approaching the range. Two conclusions can be drawn. For “thick” targets, heating is more pronounced at the lower energy side, i.e. below the Coulomb barrier, and consequently not in the activated (and thus analyzed) part of the sample. The most efficient back-side cooling is for a sample thickness not exceeding the range. Remember that for trace element determinations in the bulk of a sample one has to always irradiate “thick” samples and standards. For surface characterization of thin layers (nm to \(\mu\)m) the heat release is several orders of magnitude lower. It is obvious that also the heat release in the substrate should be considered.
Figure 5 Heat (i.e. power) release as a function of the depth for an aluminum target irradiated with 10-MeV protons. The proton energy decrease is also indicated. The heat release in mW µA⁻¹ µm⁻¹ is equal to the numerical value of the stopping power expressed as keV µm⁻¹, according to Equation (28).

6.3 Target Holder

CPAA has been applied for solid samples (massive or powdered), such as semi-conductors, metals and alloys, ceramics, geological materials, and solid environmental samples (aerosols, soils). It has not been applied for aqueous solutions because optical (atomic) and mass spectrometric methods of analysis are much more suited.

A simple target holder design is a water cooled copper or aluminum base plate, on which a "thick target" is mounted, that can be irradiated in the vacuum system of the cyclotron. For surface characterization, the target should be backed (e.g. by aluminum for proton activation) to obtain "thick" target conditions, and so avoid activation of the target holder. For powdered samples with poor thermal conductivity, irradiation in a helium atmosphere is recommended.(30) An annotated example is shown in Figure 6.

6.4 Direct Beam Intensity Monitoring

Although the beam intensity $I$ is quantified a posteriori by $I$-monitors (see below), direct $I$-monitoring is necessary to keep it constant during irradiation, a prerequisite for obtaining Equation (11). Therefore the target holder should be electrically insulated ($>10^{10} \Omega$) from the beam transport system. Moreover, the cooling water should be deionized, as this is the case for the cooling system of the cyclotron. The target holder (i.e. A + B or A + C in Figure 6) is connected to the ground by an ammeter that will measure in the µA range, as shown in Figure 7(a). During irradiation the target tends to charge positively,

---

**Figure 5** Heat (i.e. power) release as a function of the depth for an aluminum target irradiated with 10-MeV protons. The proton energy decrease is also indicated. The heat release in mW µA⁻¹ µm⁻¹ is equal to the numerical value of the stopping power expressed as keV µm⁻¹, according to Equation (28).

**Figure 6** Target system for irradiation in a helium atmosphere.(30) A titanium foil separates the vacuum of the cyclotron from the helium atmosphere. A powdered target is loaded in a dedicated target holder (B), together with a beam intensity monitor foil and an aluminum foil. A disk target is loaded in a dedicated target holder (C), together with a beam intensity foil and an aluminum foil. Powders are loaded from the back-side (B) and, after irradiation, quantitatively unloaded from the front side. Disk targets with good thermal conductivity are also water cooled from the back-side. The target holder (B or C) is brought in a water cooled set-up (A), which is evacuated and filled with helium. (Reproduced by permission of Elsevier Science, from N. De Brucker et al., *Anal. Chim. Acta*, 220, 93–102 (1989).)
which is balanced by the “electron” current measured. By impact of the CPs on the target, secondary electrons are emitted towards grounded parts (e.g. diaphragm) of the beam transport system, which causes positive systematic errors in the \( I \)-measurement. To avoid emission of secondary electrons (and their positive systematic errors for \( I \)-measurement) two experimental set-ups are used. A ring-shape electrode at negative potential (−100 V, as the electron energy does not exceed 100 eV) is inserted between the diaphragm and the target, as shown in Figure 7(b). Alternatively, the target holder is electrically connected to a tube, preventing the escape of secondary electrons over a wide spatial angle, as shown in Figure 7(c). A suitable diaphragm prevents the beam from hitting both devices as well as the target holder itself.

6.5 Quantitative Beam Intensity Monitoring

Knowledge of the ratio of the beam intensity for standard and sample (Equations 18, 22–24) is necessary for quantitative analysis in CPAA. There are three reasons for not using direct beam intensity measurement: (1) no absolute beam intensity data are required, (2) to obtain accurate data (no systematic errors due to secondary electrons and/or due to the beam hitting the target holder), and (3) to obtain precise data at low beam intensities (which is mostly the case for standards) compared to the blank. Sample and standard are covered prior to irradiation with a “thin” foil (i.e. \( I \)-monitor) of exactly the same thickness. After irradiation both \( I \)-monitor foils are measured. From Equation (17) the ratio of beam intensities, \( I_s/I_x \), is given.

Figure 7 Direct beam intensity monitoring: emission of secondary electrons causes systematic positive errors (a) that can be avoided by a ring shape electrode at negative potential (b) or a tube preventing escape of secondary electrons over a wide spatial angle (c). (Reproduced by permission of Wiley, from K. Strijckmans, ‘Charged Particle Activation Analysis’, in Chemical Analysis by Nuclear Methods, ed. Z.B. Alfassi, J. Wiley & Sons, Chichester, 1994.)
by Equation (29).

\[
\frac{I_x}{I_s} = \frac{A_s}{A_x} \left( \frac{1 - e^{-\lambda t_s}}{1 - e^{-\lambda t_x}} \right) \tag{29}
\]

where \( I \) is the beam intensity; \( A \) is the activity at the end of irradiation; \( \lambda = \ln(2)/t_{1/2} \), the decay constant of the radionuclide (where \( t_{1/2} \) = half-life); and \( t \) is the irradiation time. The subscripts \( x \) and \( s \) refer to the sample and standard, respectively.

Pure metal foils are the obvious choice as \( I \)-monitors because they are: (1) good thermal conductors, (2) mono elemental (the \( \gamma \)-spectra obtained are simple and thus less subject to spectral interference), and (3) available in different thickness.

During irradiation of the \( I \)-monitor, recoil nuclides are formed that may leave the \( I \)-monitor and enter sample or standard. These recoil nuclides may interfere with the measurement of the sample (or standard) activity, by nuclear interference (if the \( I \)-monitor foil is the analyte element, which is the worst possible choice) or by spectral interference. Therefore, a catcher foil is inserted between the \( I \)-monitor and the sample or standard that is not activated, e.g. aluminum for proton irradiation.

Sometimes several extra foils are inserted between the \( I \)-monitor and sample or standard to reduce the energy to just below the threshold energy or Coulomb barrier of an interfering reaction. This is also the case for a series of standards, when the samples are etched after irradiation (section 8.2).

7 ACTIVITY MEASUREMENT

Section 7.1 explains which radionuclides are formed by CP induced reactions, and gives arguments for measuring \( \gamma \)-spectra, where possible. If this is not possible, measuring the decay curve of annihilation radiation is described. Sections 7.2 and 7.3 give more details about instrumentation.

7.1 Radionuclides Formed and Decay Radiation Measured in Charged Particle Activation Analysis

CP induced reactions produce radionuclides that decay by positron emission and/or electron capture (EC) because they contain one proton in excess compared to stable nuclides. Figure 4(b) shows stable nuclides \( ^{12}\text{C}, ^{14}\text{N}, ^{16}\text{O} \), for which the number of protons \( Z \) equals the number of neutrons \((A - Z)\). In contrast, \( ^{14}\text{O} \) formed by the \( ^{14}\text{N}(p,n)^{14}\text{O} \) reaction is unstable, because of an unbalanced proton/neutron number \( (8/6) \). \( ^{14}\text{O} \) decays by positron emission, i.e. transmutation of a proton into a neutron (that stays in the nucleus), a positron, and a neutrino, both of which are emitted.

In this way a stable nuclide \( ^{14}\text{N} \) is formed again. A positron \( (\beta^+) \) is a positive electron, the anti-matter of an electron. A neutrino has no charge and a negligible mass, and consequently is nearly impossible to detect. The difference in energy level between the unstable radionuclide \( ^{14}\text{O} \) and the excited state of the nuclide \( ^{14}\text{N} \) \((E_{\text{exc}}) \) is randomly distributed between the positron and the neutrino. The excited state of \( ^{14}\text{N} \) further decays to the ground state by photon emission, i.e. \( \gamma \)-rays. Consequently, the energy spectrum of a positron is continuous, from zero to a specific maximum energy \((E_{\text{max}}) \), while \( \gamma \)-rays are mono-energetic. To identify radionuclides (i.e. qualitative analysis) specifically (i.e. without interferences), \( \gamma \)-spectrometry is preferred.

An alternative to positron emission is EC (or \( \epsilon \)). As the decay radiation produced is Auger electrons and/or X-rays, which can easily be absorbed by the sample itself, (in contrast to the \( \gamma \)-rays) they are not used in CPAA.

A limited number of positron emitters decay directly to the ground state without \( \gamma \)-emission. This is the case for the determination of light elements (boron, carbon, nitrogen, oxygen), which is actually the most important application of CPAA. As can be seen from Figure 4(b), the above mentioned reaction is an exception: \( ^{15}\text{O} \) (determination of N), \( ^{13}\text{N} \) (determination of C and N), and \( ^{11}\text{C} \) (determination of B and N) are all pure positron emitters. This is also the case for \( ^{18}\text{F} \) (determination of O). Selective and sensitive measurement of positron emitters is possible by measuring their annihilation radiation. In positron annihilation a positron loses its kinetic energy, annihilates with an electron, and two annihilation photons \((\gamma \text{-rays}) \) are emitted in opposite direction. According to the mass–energy equivalence law, their energy is \( 511 \text{ keV} \), corresponding to the mass of an electron at rest. It is obvious that the information about the characteristic maximum energy (and thus the identity of the radionuclide) is lost during the annihilation process. The positron emitter must now be identified by its characteristic half-life. Therefore the activity of a mixture of positron emitter(s) is measured as a function of time, i.e. the decay curve. Decay curve analysis is detailed in section 9.2.

7.2 \( \gamma \)-Spectrometry

\( \gamma \)-Spectrometry can be performed by an NaI scintillation detector and a Ge semiconductor detector. To reduce spectral interferences as much as possible, only a Ge detector is used because of its superior energy resolution characteristics compared to the NaI detector. The Ge detector is a diode, reverse biased. One \( \gamma \)-ray interacts with the detector by Compton scattering or the photoelectric effect. The photo- or Compton electron formed causes ionization in the detector and many electron–positive-hole pairs are formed. The electrons and
positive holes are collected by the electric field applied, and produce a charge pulse. The charge is proportional to the γ-energy (photoelectric effect) or lower (Compton scattering). After linear amplification and analog-to-digital conversion (ADC), the multi-channel analyzer shows a digital spectrum with photopeak(s) corresponding to the γ-energy/energies, and, at the lower energy side, a Compton continuum.

The characteristics of a Ge detector are described by the performance towards the 1333-keV γ-ray of 60Co: (1) energy resolution, i.e. the full width at half-maximum (fwhm), 2 keV or better; (2) peak to Compton ratio, i.e. the ratio of the photopeak height to the Compton continuum at 1 MeV, typically 40–60; and (3) relative detection efficiency, i.e. relative to a 76μm at 1 MeV, typically 40–60%; and (4) relative detection efficiency, i.e. relative to a 76μm at 1 MeV, typically 40–60.

The energy calibration of the γ-spectrometer is carried out by calibration sources covering the whole energy range of interest (0.1–2 MeV), such as 244Am, 57Co, 24Na and 60Co. Activity calibration, i.e. determination of the absolute detection efficiency, is not necessary as absolute activity measurements are not required in CPAA (Equations 18, 22–24). Quantitative analysis requires correction for “counting losses” or “dead-time”, i.e. the spectrometer does not detect (is “dead”) a γ-ray (a “count”) because it is still processing the previous one. As radioactive decay is random, the counting-loss probability increases exponentially with the count rate. Therefore, the dynamic range of a γ-spectrometer is limited. Different systems are in common use for the dead-time correction: the “live-timer”, which is standard in any spectrometer but not applicable for short-lived isotopes, in contrast to the very simple “pulser method”, the dead time stabilizer (DTS), and the loss-free counting (LFC) module.

Samples and standards should be measured at the same detection efficiency, which is determined by the source-to-detector geometry, and self-absorption as well. For instrumental analysis of solid samples, it is mostly sufficient to measure samples and standards positioned at exactly the same distance from the detector, with the irradiated side towards the detector. Because of the limited range of CPs in matter, the self-absorption of sample and standard (and hence the difference in self-absorption) is very low or negligible, except for very low γ-energies and high-Z targets. This can be roughly estimated, assuming a point source absorbed by half the range, using mass attenuation coefficients compiled by Hubbell.

For radiochemical analysis (section 8.4) the geometry and self-absorption of the sample (solution or precipitate) can be quite different compared to the standard (a “thick” or “thin” foil). The relative (i.e. sample vs standard) detection efficiency has to be determined experimentally. A tracer, preferably the mono-elemental standard or, if not, a radionuclide emitting almost the same γ-energy, is irradiated, measured in the standard geometry, brought into the same chemical and physical form as the sample, and measured again. The chemical form should be as similar as possible with respect to its atomic number, Z.

7.3 Positron Counting

Pure positron emitters have to be measured by their 511-keV annihilation photons, emitted in opposite direction (section 7.1). Although this can be measured by a Ge detector, it is more convenient to use an NaI detector because: (1) the detection efficiency is at least equal, even for small NaI detectors, compared to the state-of-the-art Ge detectors; (2) an NaI detector is much cheaper than a Ge detector; (3) a Ge detector should be cooled with liquid nitrogen but an NaI detector does not need cooling; (4) there is no advantage in obtaining the better energy resolution of the Ge detector, as all positron emitters produce annihilation radiation of the same energy. Therefore, there is no need for a multi-channel analyzer. It is sufficient to use a single-channel analyzer that selects all γ-rays measured in the 0.4–0.6 MeV energy interval.

The signal-to-noise ratio can also be improved by the use of a γ–γ coincidence set-up. Two NaI detectors are used, facing each other, and the β+ emitter is placed between them. The annihilation photons are emitted in opposite direction, and can be detected simultaneously in both detectors. A coincidence circuit selects all simultaneous events (typically within 40 ns). The system is very insensitive for all γ-radiation other than annihilation photons, even if present in the sample, for positron sources outside the gap between both detectors and for background radiation or random noise. However, the detection efficiency is lower compared to a single detector, because both annihilation photons should produce a photoelectric effect in each detector. The detection efficiency sharply decreases when the source is moved away from the space between the two detectors. Identical geometry for both sample and standard is still more important than for Ge spectrometry. The relative (sample vs standard) detection efficiency can be determined experimentally, as explained in section 7.1, using a pure positron source like 68Ge/68Ga (t1/2 = 270 days), which is commercially available.

For tuning the set-up (energy range, coincidence time interval) and checking its stability (constant detection efficiency), long-lived positron sources like 22Na (t1/2 = 2.6 years, also a γ-emitter) or 88Ge/88Ga (t1/2 = 270 days) can be used.

As annihilation only occurs after the positron slows down, the positron source should be enveloped by an absorber (of any value of Z). An absorber thickness
8 PROCEDURE

The conceptual and experimental procedures to be followed for trace element determinations in the bulk of a sample and for surface characterization are described as a whole, making reference to the other sections if appropriate. The common part is given in the next section. Finally, a radiochemical separation can improve the detection limit and precision.

8.1 General

The first step is to make an appropriate choice for nuclear reaction and CP energy to avoid possible nuclear, spectral, or matrix interference (section 4). For trace element analysis in the bulk of a sample the matrix is the main component of the sample; for surface characterization the main component is the substrate of the surface layer.

The tools are data for threshold energy, Coulomb barrier, cross-section or TTY (if these are not available then Equation 9 may be used), stopping power or range, and a chart of the nuclides (sections 2 and 3). Examples are given in section 4. Activation curves can be obtained experimentally as described in section 3.4.

To preserve the advantage of CPAA as an “absolute” or “independent” method, no standards may be used that are certified or calibrated by another method. Mono-elemental standards are ideal. Therefore, pure elemental standards (i.e. metals) or a pure compound with exactly known stoichiometry can be used to obtain accurate data for the mass fraction for the analyte element as well as for stopping power. The standard should be stable during irradiation (when heating occurs, as described in section 6.2) in a vacuum. Some organic and hygroscopic compounds cannot be used, not only because the mass fraction of the analyte element increases during irradiation, but more importantly because the stopping power decreases as the hydrogen content decreases. Indeed, the stopping power for hydrogen is 3–5 times higher than for the other elements (Figure 1c). Both phenomena lead to positive errors. Not only should the standard itself be stable during irradiation, but so also should the radionuclide formed or any compound of it. Boric acid is a good boron standard for the nuclear reaction \(^{10}\text{B}(p,n)^{11}\text{C}\), but not for \(^{10}\text{B}(p,\alpha)^{7}\text{Be}\), as the \(^{11}\text{C}\) formed volatilizes as carbon dioxide. Boron metal must be used for the latter reaction. To avoid nuclear or spectral interferences the mono-elemental standard should be very pure. Ideally, only activity from the analyte element is found in the γ-spectrum or decay curve.

For irradiation, samples and standards are covered with an I-monitor foil, a catcher foil for recoil nuclides from the I-monitor foil, and, if necessary, extra foils for fine tuning the incident energy on sample or standard (section 6.5). Never use the analyte element as an I-monitor. The thickness of the catcher foil is at least equal to the range of the recoil nuclides. The energy of the recoil nuclides can be calculated exactly, but is always smaller than \(E_a + Q\). So the maximum range can be calculated as described in section 2.3. In practice a few μm is sufficient.

The use of an I-monitor, a catcher foil and more extra foils slightly reduces the incident energy on the
sample and the standard. Using the definition of stopping power (Equation 1) this can be calculated by using Equation (31).

\[ E_o = E_i - SD \]  

(31)

where \( E_o \) is the outgoing energy, in MeV; \( E_i \) is the incident energy, in MeV; \( S \) is the mass stopping power, in MeV g\(^{-1}\) cm\(^2\); and \( D \) is the mass thickness of the “thin” foil, in g cm\(^{-2}\). For each foil with mass thickness \( D_i \), the outgoing energy \( E_o \) of the previous foil is the incident energy \( E_i \) of the following foil. For “thin” foils the stopping power is considered constant in the energy interval \( E_o - E_i \). The mass thickness of the foils has to be determined experimentally by weighing and measuring its surface, rather than using its nominal or measured thickness multiplied by a tabulated mass density. For an aluminum foil 10 \( \times \) 10 cm\(^2\) with a 5-\( \mu \)m nominal thickness, measured with an uncertainty of 0.1 cm and 0.1 mg, the mass thickness yields 1.35 \( \pm \) 0.03 mg cm\(^{-2}\). The precision on the energy, calculated by Equation (1), yields about 3 keV for \( \alpha \)-particles (\( S \approx 100 \text{ MeV g}^{-1}\text{cm}^2 \)), which is largely sufficient. The precision is much better for protons, deuterons, and helium-3 particles, for foils with an atomic number higher than that of aluminum (i.e. foils with a lower stopping power) or for foils with a mass density higher than aluminum or thicker than 5 \( \mu \)m (i.e. foils with a higher mass).

Irradiations are carried out under vacuum or helium, monitoring the beam intensity as described in sections 6.3 and 6.4. For the standards, shorter irradiation times and/or beam intensities are applied, as the amount of analyte element irradiated is orders of magnitude higher than for the sample. To avoid radioactive contamination from the standards, it is good practice to irradiate the samples prior to the standards.

After irradiation, a waiting time, also called the decay or cooling time, is observed for sample handling, chemical etch (section 8.2) or radiochemical separation (section 8.4).

Measurements of samples and standards are done by \( \gamma \)-spectrometry (section 7.2) or positron counting (section 7.3), \( \beta \)-monitors by \( \gamma \)-spectrometry. Time management is important to improve signal-to-noise ratio (and thus the detection limit and repeatability) and to avoid or suppress spectral or matrix interferences. For an irradiation time equal to one half-life one obtains half of the activity for an infinite irradiation time (Equation 9). For a waiting time equal to one half-life one obtains half of the activity for no waiting time (Equation 9). Shorter irradiation or waiting times decrease the analyte activity compared with short-lived interfering activities. Longer irradiation or waiting times decrease the analyte activity compared with long-lived interfering activities. The same holds for the measuring time, simply replacing “activity” by “number of counts” (see Equation 34 in section 9.3). Data handling is described in section 9.

8.2 Trace Elements in the Bulk of a Sample

To obtain high sensitivity, samples and standards are irradiated at an energy slightly above the maximum cross-section, i.e. when the TTY reaches a plateau. For the determination of iron by the \( ^{56}\text{Fe}(p,n)^{56}\text{Co} \) reaction (Figure 3b) the proton energy is about 15–20 MeV. The initial choice is further refined or rejected by considerations of nuclear, spectral and matrix interferences, as explained in section 8.1.

Samples and standards are always “thick” targets (thicker than the range, section 5.2). However, for back-side cooling the thickness should not exceed the range too much (sections 6.2 and 6.3). For massive samples (not powders) interference from the surface can be avoided by chemical etch prior to irradiation, at least if further surface contamination can be avoided until the end of irradiation. It is obvious that chemical contamination after irradiation does not interfere any more. For the determination of carbon, nitrogen or oxygen the sample may be contaminated after chemical etch and prior to irradiation. For example, the alumina layer found in air may interfere with trace oxygen determination in the bulk of pure aluminum. The alumina layer is also activated and the oxygen content is found to be too high. Chemical etch after irradiation is then the method of choice. The activated surface layer will be removed and replaced by an inactive surface layer that will no longer interfere. The thickness to be removed is not determined by the thickness of the oxide layer, but by the range of the recoil nuclides formed from oxygen in the alumina layer. The energy of the recoil nuclides is less than \( E_o + Q \), and its range can be calculated as described in section 2.3. It is good practice to check experimentally the apparent oxygen content compared with the amount removed from the surface layer: a steep decrease followed by a plateau at a few \( \mu \)m. Chemical etch after irradiation reduces the incident energy on the sample, i.e. the sample as it will be measured. Etching the standard is not convenient and may be impossible for powdered standards. A set of two standards is irradiated at two different energies by insertion of additional foil(s) between the recoil foil and the standard. That energy interval should cover the incident energies for all the samples after etch, which is not always very reproducible. Then the standard activity for each individual sample can be obtained by linear interpolation of the set of standards. Energy calculations are done using Equation (31). The mass thickness of the removed surface layer can be obtained by measuring the dimensions of the sample.
and weighing prior to irradiation, rather than etch, and after etch. Linear interpolation is justified if the incident energy is chosen in the plateau of the TTY.

8.3 Surface Characterization of Thin Layers

To obtain high sensitivity, samples and standards are irradiated around the energy for maximum cross-section. If Equation (23) is applied, the cross-section should be nearly constant for the energy interval of the “very thin” standard (sections 5.1 and 5.3). The initial choice is further refined or rejected by considerations of nuclear, spectral and matrix interferences, as explained in section 8.1.

For surface layer characterization samples are always “thin”; the standards can be “thick”, “thin”, or “very thin”, each requiring appropriate standardization, as explained in section 5.3. A “thin” standard does not mean that the standard should be comparable to the sample thickness (the order of magnitude is µm–nm), or that its thickness or composition should be determined by another method. “Thin” standards are typically 10–100µm thick. Their mass thickness has to be determined experimentally by weighing and measuring the surface, as explained in section 8.2. For a standard that is not available as a foil, a virtual “thin” standard can be used. A set of two “thick” standards is irradiated at two different energies, one without and the other with an additional foil between the recoil foil and the standard. The difference in standard activities is equal to a “thin” standard with a thickness that yields the same energy reduction as the additional foil. The mass thickness of the virtual “thin” standard can be calculated from Equation (32).

$$D_s = D_f \frac{S_f}{S_s}$$  \hspace{1cm} (32)

where the subscripts s and f refer to the virtual “thin” standard and the foil covering the second “thick” standard, respectively. As the virtual “thin” standard activity results from a small difference in activities, both standards should be measured with good counting statistics. Moreover the virtual “thin” standard should be as thick as possible and still comply with the “nearly constant cross-section” condition.

Heating of the sample during irradiation is described in section 6.2. To avoid activation of the target holder, samples and “thin” standards should be backed by a “thick” thermal conductor, e.g. aluminum for proton irradiation.

8.4 Radiochemical Separation

Instrumental analysis is possible if spectral or matrix interference can be avoided by an appropriate choice of the incident energy and/or the measuring conditions (section 4) and/or time management for irradiation and measurement (section 8.1). If not, the radionuclide B formed from the analyte element A has to be separated radiochemically from an interfering radionuclide D formed from an interfering element C. The latter technique is called radiochemical analysis. This section deals with some major differences between a radiochemical separation and a common chemical separation as used in nonnuclear methods of analysis.

For most CP induced reactions, the atomic number of the radionuclide B is different from that of the analyte element A. This is the case for (p,n), (p,a), (d,n), (d,a), (3He,n), (3He,d), (a,n), and (a,d) reactions, but not for (p,d) and (3He,a) reactions (section 3.4 and Figure 4). The chemical separation to be developed for CPAA is thus different from that for all nonnuclear analytical methods and for some other methods based on activation analysis, such as thermal and fast neutron activation analysis using the (n,γ) or (n,2n) reaction, respectively, and photon activation analysis using the (γ,n) reaction. In principle, it is also not necessary to separate the matrix, but rather the radionuclide(s) formed from the matrix element(s). Again, the atomic number of a radionuclide formed from a matrix element is generally different from that of the matrix element itself. Considering only the chemical separation involved, CPAA is an independent analytical method, not subject to the same systematic errors as other analytical methods. Radiochemical separation has three important advantages over conventional chemical separation:

1. An inactive carrier can be added for the elements to be separated (B and D). This avoids the difficulties of a chemical separation at the trace level.
2. Reagent impurities (or blanks) do not influence the detection limit capabilities of the analytical method.
3. Separations need not be quantitative or even reproducible (see section 8.4.2).

For the choice and development of a radiochemical separation the following points have to be considered:

1. Selectivity of the separation. As pointed out in section 4, the induced matrix activity (D) can be orders of magnitude higher than the activity to be measured (B). It is not possible to resolve such a low activity in the presence of such a high activity, as the dynamic range of the measuring equipment is limited (sections 7.2 and 7.3). Therefore the decontamination factor (the ratio of D before separation to that after separation) should be up to $10^4$.
2. Quantitative nature of the separation. Quantitative recovery of B is to be preferred (99% or more).
If the separation is not quantitative and not even reproducible, then determination of the yield for each individual separation is possible. Two approaches can be followed: the addition, before separation, of an accurately known amount of an inactive/active carrier and measurement of the mass/activity of the carrier after separation. It is obvious that the radionuclide added and the analyte radionuclide should be different isotopes of the same element.

3. **Speed of the separation.** To obtain an optimum detection limit, the time needed to perform the whole separation procedure should not exceed a few half-lives of the radionuclide to be measured.

4. **Inactive carrier.** It is not only an advantage, but mostly also a necessity, to add inactive carriers of the elements to be separated. Indeed, if the atomic number of the radionuclide B is different from that of the analyte element A (which is usually the case; see above), this radionuclide B is produced “carrier free”. As the number of radionuclides is given by

\[ N = \frac{A t_{1/2}}{\ln(2)} \]  

where \( N \) is the number of radionuclides, \( A \) is the activity (in Bq) and \( t_{1/2} \) is the half-life (in s), the amount of substance is \( 10^{-16} \text{mol} \) for \( A = 1 \text{kBq} \) and \( t_{1/2} = 1 \text{day} \). It is clear that if there is no accidental addition of inactive element B (e.g. as impurity in the matrix or reagents) it is not possible to separate chemically such a low mass.

5. **Detection efficiency of measurement.** To obtain a high sensitivity, the activity should be measured after separation with the highest possible detection efficiency. This is also determined by the geometry (size and distance from the detector) of the source. Separation procedures ending with volumes of solution are less reproducible geometrically. Obtaining a good precision and selectivity. These radiotracers are preferably produced by thermal neutron activation, if such a facility is available, rather than by CP activation. Indeed, production by, for example, a \((p,n)\) reaction yields a radiotracer that has to be separated from the target material, whereas for production by an \((n,y)\) reaction the target material can be used as the inactive carrier. The tracer has to be brought to the same chemical form as the radionuclide to be separated. This is often not possible for the dissolution step preceding the actual separation procedure. So, the choice of the dissolution procedure should guarantee quantitative recovery of the radionuclide to be measured.

6. **Repeatability of the measurement.** The repeatability of the measurement is determined by the counting statistics and also by the possibility of reproducing measurements with exactly the same detection efficiency. The former is expressed as the relative standard deviation calculated from counting statistics (i.e. \( C^{-1/2} \), where \( C \) is the number of counts measured). For a high detection efficiency, one has to use a small source to detector distance, which is less reproducible geometrically. Obtaining a good repeatability and a high detection efficiency are thus contradictory demands.

7. **Self-absorption of the source.** Self-absorption of the source is in principle no problem, as long as the absorption is identical for all samples and standards, which is mostly the case for instrumental analysis (section 7.2). Self-absorption can be important for low-energy \( \gamma \)-rays or for sources containing components of high atomic number.

8. **Separation of the matrix.** Although in principle not necessary, it may be convenient to separate the (inactive) main matrix components and so reduce the mass of material involved in the separation procedure. The following separation process is then faster, leads to smaller volumes of solution or precipitate and allows further evaporation of a solution to a smaller volume if necessary. As a consequence, the detection efficiency is improved and the self-absorption is lowered substantially or becomes negligible.

9. **Health physics.** The activity level required to perform precise measurements (i.e. at the kBq level) provides no health physics risk, as doses are of the order of \( \text{nSv h}^{-1} \). The induced matrix activity, however, may be much higher. It is good practice to first separate the main matrix activity, choosing a procedure that limits manual intervention to the strict minimum. Ion exchange chromatography, for instance, is a better choice than manual solvent extraction.
in volume to the reference) is taken and the yield for the ion to be precipitated can be calculated very precisely. To check coprecipitation (e.g. of matrix activity) the activity of the precipitate is measured. As the detection efficiency is not comparable with that of the reference measurement, the result has to be considered as an estimate. This is largely sufficient for the purpose of evaluating the selectivity of this separation.

There is no need to apply radiochemical separation to mono-elemental standards. However, standards and samples have to be measured at identical detection efficiency. Therefore the standards are brought into exactly the same geometrical form as the samples after separation. If the last step of a separation is ion chromatography, the standards are dissolved and the total volume is brought exactly to the volume of the eluate. Possible differences in self-absorption have to be considered. The eluate may contain an acid other than the one used to dissolve the standard; the eluate may contain only the added inactive carrier (B), whereas the standard contains a larger amount of the analyte element (A).

9 DATA HANDLING

This section follows chronologically from the previous one. Once the irradiation and measurement data (γ-spectrum or decay curve) have been collected, they have to be analyzed and the result (i.e. trace element concentration in the bulk of a sample, mass thickness of a surface layer, composition of a surface layer) has to be calculated.

9.1 γ-Spectrum Analysis

The manufacturers of γ-spectrometers provide suitable programs to resolve the spectrum, i.e. find the significant peaks and calculate their energy, resolution (i.e. fwhm, and comparison to the detector characteristics), net count area, standard deviation (from counting statistics), and detection limit (in number of counts). Once such data have been obtained, it is not sufficient to search only for the most intense γ-ray of the analyte radionuclide. The whole spectrum has been analyzed, starting at the high energy side of the spectrum, using databases with γ-energies and γ-intensities (number of γ-rays emitted per 100 disintegrations). It should be noted that the detection efficiency of a γ-detector is a function of the γ-energy. For high energy γ-rays ($E_γ > 1022$ keV) single and double escape peaks can be observed at an energy equal to $E_γ - 511$ keV and $E_γ - 1022$ keV. Two intense γ-rays, or γ-rays emitted in cascade, can give rise to sum-peaks. All this can provide useful information concerning the main, minor or trace components in the matrix, which can cause nuclear, spectral and/or matrix interference. Peak broadening is evidence of spectral interference, although no peak broadening does not imply the absence of spectral interference. In case of doubt, decay curve analysis (section 9.2) can be applied to check for spectral interference. All possible reactions on all stable isotopes for an element observed in the spectrum have to be checked, as explained in section 3.4.

Erdtmann and Soyka published a table with γ-energies and γ-intensities, ordered by radionuclide as well as energy. This database is also available at the Lund Nuclear Data WWW Service (Lund University, Sweden). The production mode can be specified as “CP reaction”. The database is not updated. The NuDat (Nuclear Data) database is retrievable by, and can be sorted by, radionuclide, half-life, γ-energy and/or γ-intensity. The NuDat database at the Lund Nuclear Data WWW Service (Lund University, Sweden) was last updated in January 1996, and will not be updated in the future. In 1999, it is actually the only NuDat base where the production mode can be specified as “CP reaction”. The NNDC databases are updated three to four times a year, and mirrored at IAEA and NEA. The same database is also obtainable as a PC/DOS program: PCNUDAT. The Table of Isotopes (TOI) database is available as a book and a CD-ROM, and on the Internet at the Lund Nuclear Data WWW Service (Lund University, Sweden). Both are updated yearly.

9.2 Decay Curve Analysis

Positron counting, followed by decay curve analysis, is only applied when the analyte radionuclide is a pure positron emitter. Unfortunately, all CP induced reactions induce positron emitters, and consequently the decay curve may be very complex. In contrast to γ-spectra, which may contain hundreds of γ-rays, the number of components in a decay curve is rather limited (<10). Ideally, a decay curve analysis should answer the questions: (1) how many components are present; (2) what is the half-life of each component; and (3) what is its activity? As most positron emitters are also γ-emitters, their possible presence in the decay curve can be checked by γ-spectrometry and avoided by a proper choice of irradiation and measurement conditions. Moreover, the number of pure positron emitters is rather limited and the number and identity of possible components in the decay curve are mostly known. A decay curve analysis that provides an answer to the second question (qualitative analysis) and the third question (quantitative analysis) is acceptable. By weighed linear regression analysis the third question can be answered, the goodness of fit indicating if the initial assumptions about the number and half-life of
the components are correct. The half-life cannot be fitted because the decay curve is a sum of exponential functions, thus the half-life parameter is not linear. Assuming an initial value for the half-life, the problem can be linearized, and so, by iteration, the best half-life can be fitted. Components that are not present can be rejected because their activity is extremely low or negative. Such an algorithm has been developed by Cumming, and applied successfully. More recently, Prony’s improved method has been implemented, tested extensively, and compared to Cumming’s method by Schreurs et al. This method also answers the first question, but requires data points equidistant in time.

9.3 Quantitation

Standardization is done in a relative way, the sample and standard being irradiated and measured under, principally, identical conditions. As these identical conditions are not fulfilled in practice, some corrections or normalizations are performed first.

The number of counts measured are corrected for:

1. Counting losses (dead-time), according to sections 7.2 and 7.3, and background (for γ-spectrometry this is mainly the Compton continuum of other γ-rays), using a decay curve analysis program.

2. Differences in measurement (\( t_w, t_m \)) conditions (Equation 34), using a decay curve analysis program. The normalized count rate represents the count rate for a decay time zero, i.e. at the end of irradiation. In Equations (22–24) it can replace \( A \) for equal detection efficiency of sample and standard.

\[
R = \frac{\lambda C e^{\lambda t_w} - e^{-\lambda t_m}}{1 - e^{-\lambda t_m}}
\]  

(34)

where

\( R \) = normalized count rate, the number of counts per unit time;

\( \lambda = \ln(2)/t_{1/2} \) decay constant (where \( t_{1/2} \) = half-life);

\( C \) = number of counts measured;

\( t_w \) = waiting time;

\( t_m \) = measuring time.

3. Differences in irradiation conditions \((I, t_i)\), corrected for by Equation (18), (22), (23) or (24) (sections 5.2 and 5.3).

4. If applicable, differences in detection efficiency, due to different sample/standard-to-detector geometry and/or self-absorption for sample versus standard (section 7.2).

Finally, difference between the mono-elemental standard and the sample is corrected by Equation (19), (20) or (21) for trace element analysis and Equation (22), (23) or (24) for surface characterization, as explained in sections 5.2 and 5.3. Each individual result can be completed by the standard deviation, calculated from counting statistics, which can be compared to the reproducibility.

For surface characterization, primarily a partial mass thickness is obtained. The total mass thickness can be calculated if the mass fraction (or stoichiometry) is known. The thickness can also be calculated if the mass density is known. Be aware that the mass density can be much lower than the tabulated values, because less dense structures can be deposited, depending on the production mode. The partial mass thickness can also be used to calculate the mass fraction if the total mass thickness is known or if all mass fractions are determined. Also the stoichiometry can be calculated from partial mass thickness data.

10 PERSPECTIVES

10.1 Charged Particle Activation Analysis

During the last two decades CPAA has proved its outstanding capabilities in trace element determinations in solid samples. For the determination of light elements CPAA is still unique. Blondiaux et al. reviewed its applications. Recently CPAA has been proposed for surface characterization and experimentally validated. This method, despite its inherent limitations, is expected to be a reference method, because of its outstanding accuracy, precision and detection limit.

10.2 Charged Particle Activation for the Development of Other Analytical Methods

In addition to CPAA, the production of carrier-free (section 8.4) radionuclides by charged particle activation (CPA) can be a magnificent tool in the development of other analytical methods. A radioactive tracer is a molecule labeled with a radionuclide. A carrier-free radionuclide or tracer is one with a high specific activity, i.e. activity per mass unit. At very low concentrations some analytical methods require preconcentration or chemical separation prior to measurement. These methods can be developed using these tracers, because the extremely low amount of analyte is almost unchanged. The tracer experiments can be performed at the same concentration levels as the final analyses. The activity levels required are very low, and do not present a significant risk. Using rather short-lived radionuclides, there is no waste problem either. An example is the determination of platinum by inductively coupled plasma mass spectrometry (ICPMS), using \(^{191}\)Pt.

Chemical Analysis by Nuclear Methods: Introduction

Zeev B. Alfassi
Ben Gurion University, Beer Sheva, Israel

Chemical analysis by nuclear methods is usually an elemental analysis, i.e. it determines the contents of the various elements in the analyzed sample but cannot tell in what chemical form (compounds, valence states) they are. The analysis is based on either a reaction of the analyzed element with nuclear projectiles (neutrons or accelerated charged particles, e.g. electrons, protons, heavy ions or γ-photons) (see the following articles within this section: Instrumental Neutron Activation Analysis; Instrumental Neutron Activation Analysis: Gamma Lines Table; Charged Particle Activation Analysis; Cyclic Activation Analysis; Particle-induced γ-Ray Emission; PIXE (Particle-induced X-ray Emission); Radiochemical Neutron Activation Analysis; Nuclear Reaction Analysis and Scattering and Absorption of γ-Rays and Thermalization and Disappearance of Neutrons) or on the scattering of accelerated charged particles. The reaction can be written in the same form as a chemical reaction:

$$\text{Target} + \text{Projectile} \rightarrow \text{Light product} + \text{Heavy product}$$

or in the more concise form of writings of nuclear physics:

$$\text{Target (Projectile, Light product) Heavy product}$$

Thus, for example, the first production of artificial radionuclide by Joliot and Curie was done by the reaction of α-particles with aluminum metal:

$$^{27}\text{Al} + \alpha \rightarrow ^{30}\text{P} + n \quad (\alpha \text{ is the } ^{4}\text{He nucleus})$$

or in the physics notation: $$^{27}\text{Al}(\alpha, n)^{30}\text{P}$$.

The light product is similar to the projectile and can be a neutron, a small charged particle or a photon. The basis of the nuclear methods for chemical analysis via nuclear reaction (nuclear activation) is the measurement of the amount of light or heavy product formed in a known flux of projectiles for a known length of time (irradiation time). The amount produced is proportional to the number of target atoms, and hence measurement of the amount of the products yields the amount of target atoms. The amount of products formed is too small to be measured chemically (except in very rare cases), and the only way to measure them is by the nuclear physics method of pulse counting. The light product can be measured due to its energy if it is a photon or a charged particle of high kinetic energy, or due to its reaction if it is a neutron.

The common denominator of all these processes is that they must be done a very short time after formation of the product, otherwise the light product will lose either its energy or its identity by reaction with the surrounding media. Consequently, measurement of the light product must be done during bombardment of the target with projectiles. This kind of measurement is called prompt activation analysis.

A similar situation exists when the analysis is done by scattering of the projectile, and the measurement is made simultaneously with the irradiation. In this case qualitative analysis is based not on the identity of the products but rather on the kinematics of the scattering, i.e. the energy and direction of the scattered particles. Quantitative measurement is done by counting the number of scattered particles. In the case where the heavy product is radioactive, i.e. it undergoes a spontaneous nuclear transformation, its identity and amount can be measured by its radioactivity. Because the radioactivity can be measured after the end of the interaction between the target and the beam of projectiles, this method of analysis is called delayed activation analysis. Because the heavy product must be radioactive, not all elements can be measured with each projectile. However, by careful choice of the bombarding projectile, almost every element can be determined.

Because many elements are activated simultaneously, the radioactivity measurement must yield both the identity of the radioactive nuclides and their amounts. The term that is sometimes used – radioisotopes – is wrong because when saying isotopes we should say of what element, see Elemental Analysis by Isotope Dilution. Nuclide is the nuclear physics term that is parallel to “atom” in chemistry. It consists of a nucleus (composed of neutrons and protons) and electrons around it. Because the identity of radionuclides (a short term for radioactive nuclides) in a mixture usually cannot be determined from β- or β+-emission (unless there are only very few in the mixture and they differ strongly in their half-lives or energy of the β-particles), only radionuclides that also emit γ-rays can be used in activation analysis. The radionuclides used for identification are called indicator radionuclides. Only few pure β+-emitting indicator radionuclides, such as $^{32}$P, can be used in activation analysis. In this case the phosphorus should be separated from the other radionuclides in the activated sample or the other radionuclides are left to decay before the measurement. The chemical analysis by nuclear activation in which chemical separation precedes the radioactivity measurement is named Radiochemical Neutron Activation Analysis, whereas analysis by nuclear activation with direct measurement of the nuclear activity is named Instrumental, see Instrumental Neutron Activation Analysis and Instrumental Neutron Activation Analysis: Gamma.
Lines Table. Owing to the method of measurement of pulse counting, very small amounts of radionuclides can be assessed quantitatively. This and the fact that most natural nuclides are nonradioactive are the basis for the use of radionuclides as tracers in chemical analysis.

Scattering of charged particles is measured both in the forward direction (by Elastic Recoil Detection Analysis) and in the backward direction (by Rutherford Backscattering Spectroscopy). In the first years of studies mainly the scattering of light ions was studied, but later the scattering of heavier ions became more frequent. The widespread availability of 2–3-MeV accelerators made their use more popular. However, in forward scattering they are restricted to the analyses of H and D. Heavier elements can be analyzed with the beams by backward scattering or by forward scattering of heavier ions. In the recent Ion Beam Analysis Conference at Lisbon (1997) there were two papers on He-induced elastic recoil detection analysis compared to 26 papers on heavy-ion elastic recoil detection analysis. However, for routine analysis the situation is different owing to the availability of the low-energy He accelerators.

Activation by neutrons is carried out mainly in the delayed mode, where very low detection limits can be obtained. Prompt activation is used mainly for in situ and on-line analysis and for elements that cannot be determined by the delayed mode due to the product being nonradioactive or having too short or too long a half-life. An example is the determination of hydrogen and nitrogen atoms by PGNAA (prompt gamma neutron activation analysis), mainly in food samples, see Prompt \( \gamma \)-Neutron Activation Analysis.

The slowing down of high-kinetic-energy charged particles passing through matter allows not only the determination of the total concentrations of some elements but also their distribution as a function of distance from the surface, i.e. depth profiles of the concentrations of the various elements. The slowing down can change the energy of the emitted charged particle, e.g. in the reaction \( ^{10}\text{B}(n,\alpha)^{7}\text{Li} \). The energy of the \( \alpha \)-particle crossing the surface of the sample to reach the detector indicates the distance the \( \alpha \)-particle travels in the sample via the energy loss from the original energy of the \( \alpha \)-particle.

The slowing down of an impinged high-energy projectile can reduce its energy to the range where a resonance reaction can occur. Thus, by changing the original energy of the projectile, the depth profile of the concentration can be measured.

All nuclear methods, except those using radiotracers, use either nuclear reactors or ion accelerators. These are quite expensive machines that are not found in common analytical laboratories but rather in special laboratories. Many of these methods involve the cooperation of chemists and nuclear physicists.

Chromatographic techniques in industrial hygiene are defined as those separation and analysis techniques which rely on the separation of multiple chemical constituents by taking advantage of the differential adsorption, absorption, mobility, or affinity of the components in a system with a stationary phase (solid, liquid coated on solid, reactive substituted attached to solid surface, ion exchange resin, etc.) and a mobile phase (gas or liquid) which transports the separated constituents to a detector for immediate identification and possible quantitation or to a collector for later identification and possible quantitation.

By industrial (occupational) hygiene is meant that science and art which is the anticipation, identification, assessment, and control of chemical and physical hazards in the workplace (meant to include offices, places of business, retail establishments, and schools) and home. Included among those methods that make possible the identification and assessment of such hazards are those methods which are used to determine the concentration of airborne and surface chemical contaminants, as well as those which assess levels of exposure to chemical contaminants by the analysis of exhaled breath, blood, urine, or other biological samples.

1 INTRODUCTION

This article will address all the various chromatographic techniques that are employed by industrial (occupational)
hygienists as part of a strategy for assessing workplace exposure to airborne and surface-borne chemical contaminants. It will also address biological monitoring techniques, which are used by industrial hygienists and occupational health physicians to assess exposure to workplace chemical contaminants, whether through inhalation, dermal, or ingestion pathways. Finally, since industrial hygienists have become involved in assessing more than just traditional workplaces, this article will also include methods that are appropriate for determining relatively low concentrations of chemical contaminants that are found in nonindustrial environments such as schools, public buildings, retail establishments, and homes.

2 HISTORY

2.1 Origins of Chromatographic Techniques Applied to Industrial Hygiene

The technique of gas–liquid chromatography (GLC) was first described by James and Martin(1) in 1952. Two years earlier, Elkins(2) reported on a method for separating halogenated hydrocarbons by adsorption on a sorbent column and then air elution from the column. He also indicated that benzene and toluene could be similarly separated. Although not strictly gas chromatography (GC), it is clearly a chromatographic technique and probably the earliest mention of such an approach for trapping and then separating contaminant mixtures. By 1956, Peterson et al.(3) had reported the use of GC, although not identified as such, applied to monitoring the workplace environment. In 1958 Rushing(4) published an article which predicted some of the areas in which GC would be of value to industrial hygiene. History has proved his visions to be correct. That same year, West et al.(5) published an article related to air pollution monitoring but which is relevant to industrial hygiene as well. The first mentions of GC specifically in the American Industrial Hygiene Association Journal (AIHA) were in 1959(6) and in 1960.(7) As an indication of the general level of publication on chromatographic analyses in industrial hygiene, it was only first in 1960 that Chemical Abstracts initiated a section of Water, Wastes, and Air Pollutants. By 1962, that section has become Toxicology, Air Pollution, and Industrial Hygiene, and in 1972, a section covering Air Pollution and Industrial Hygiene alone was begun in Chemical Abstracts. In 1963, Altschuller(8) wrote a survey article describing GC methods in air analysis, but no compound-specific methods were identified. In 1965, a paper presented at a National American Chemical Society (ACS) Meeting addressed the analysis of a mixture of hydrocarbons in ambient air.(9) The late 1960s saw a dramatic increase in the publication of GC methods applicable to industrial hygiene, and the technique has become the single most prevalent industrial hygiene analytical technique.

Although column chromatography has been in use for most of this century, having been described by Tswett in 1906,(10) high-performance (pressure) liquid chromatography (HPLC) was developed over a period of time beginning in the mid 1960s and grew rapidly in the early 1970s. As late as 1968, an article in Advances in Chromatography(11) reported “By comparison, GC and thin-layer chromatography (TLC) made the greatest strides in recent years and such methods as column and paper chromatography have received little attention”. However, in a 1972 review article, Zweig, Moore, and Sherma(12) reported that “Modern high pressure liquid chromatography emerged as a widely used analytical technique which promises to become one of the most popular and powerful of all chromatographic procedures”. By 1974, the review Advances in Chromatography, Vol. 12,(13) included an article on the use of HPLC in pharmacology and toxicology.

Similarly, ion chromatography (IC) built on the ion-exchange chromatography which had been used extensively for inorganic separations, but the use of high pressures, small bore columns, and direct measurements of column effluent was reported by Small et al.(14) in 1975. One of the earliest papers applying IC to industrial hygiene was for the measurement of chloracetyl chloride in workplace air.(15)

Not only was Elkins one of the earliest in suggesting chromatography-like methods for workplace air monitoring, but he was also foresighted in his proposal(16) to use biological monitoring as a means of assessing human exposure to various chemicals.

A historical overview of chromatographic methods, but without reference to industrial hygiene is found in a volume edited by Ettre and Zlatkis.(17)

2.2 Organizations Developing Methods

The AIHA developed a series of hygiene guides, starting in the mid-1950s and these guides included analytical methods for the contaminants, which then became AIHA Analytical Guides. In the early 1960s, the AIHA Analytical Guides(18) had no chromatographic techniques included in them, but by 1969, GC methods for ethyl benzene and 2-hexanone were included in this compilation.

In 1974, a recently formed National Institute for Occupational Safety and Health (NIOSH) published the first edition of the National Institute for Occupational Safety and Health Manual of Analytical Methods (NMAM)(19) with the methods designated by the prefix P&C (Physical and Chemical Analytical Methods), and including
several methods that used GC. Some of these methods were carried over from the old Bureau of Occupational Safety and Health of the Public Health Service. In 1974, NIOSH sub-contracted with SRI International for the completion of the analytical methods for existing contaminants for which a Permissible Exposure Limit existed and a series of methods were published with the prefix “S” (for Standards Completion Program). In the fourth edition, the NMAM includes 467 methods which use GC, HPLC, or IC – over 80% of the total in the manual.

The laboratory of the Occupational Safety and Health Administration (OSHA) in Salt Lake City has also developed a significant number of chromatographic methods which are available to the public. The United States Environmental Protection Agency (USEPA) has developed a series of chromatographic methods directed toward the analysis of low levels of airborne contaminants which one might find in the home or school, or general ambient environment. These are designated as TO-Series (total organic) methods. Now in the literature and many more are found in internal compilations. To some extent, individual internal methods may be available to professionals, through the Industrial Hygiene Methods Exchange Network of the AIHA in Fairfax, Virginia. A number of these companies have indicated to the AIHA Methods Network which methods they have developed and these are available, upon request, directly from the company that developed them.

2.2.1 Industry Developments

Many large multinational chemical and pharmaceutical firms (e.g. Dow Chemical, Rohm and Haas, Dupont, Abbott Laboratories, American Cyanamid, BASF) have developed or modified existing chromatographic methods intended for workplace monitoring of hazardous substances. Some of these methods have been published in the literature and many more are found in internal compilations. To some extent, individual internal methods may be available to professionals, through the Industrial Hygiene Methods Exchange Network of the AIHA in Fairfax, Virginia. A number of these companies have indicated to the AIHA Methods Network which methods they have developed and these are available, upon request, directly from the company that developed them.

2.3 Overview of Improvements in Chromatographic Techniques

Dramatic improvements in chromatographic techniques for industrial hygiene have taken place since the first methods were applied in the 1950s. In the field of GC, thermal conductivity detectors, isothermal separations, and packed copper columns have been supplanted in the past 40 years by the introduction of temperature programming, high-resolution capillary columns and megabore columns, a variety of highly sensitive detectors such as flame ionization, electron capture, mass spectrometric, flame photometric, thermionic, photoionization, and Fourier transform infrared (FTIR) spectroscopy. High-speed GC has, in recent years, allowed the use of transportable gas chromatographs for making field measurements (see below).

HPLC has been dramatically improved in its sensitivity and selectivity by going from coulometric and differential refractive index detectors to multiple wavelength ultraviolet/visible (UV/VIS), diode array, mass selective, and fluorescence detectors and enhanced its separation power by having instruments that can change eluent composition among multiple components as a function of time. The development of reversed-phase columns has also increased the separation power of HPLC. An example of this enhanced sensitivity and separation power is the analysis of complex mixtures of polynuclear aromatic hydrocarbons (PAHs) found in the air in coal conversion (gasification and liquefaction) plants. Such a
compound-specific analysis, which would have been difficult, if not impossible with packed columns and thermal conductivity detectors, was reported in the late 1970s.\(^{33}\)

The entire field of HPLC has grown up during the period of maturation of industrial hygiene monitoring in the United States, and made simple many analyses that had been difficult, or insensitive, or both, prior to that.

### 2.4 Review Articles

There are periodic review articles which generally cover the entire field of analytical chemistry applied to industrial hygiene, but in which methods that use chromatographic techniques are the overwhelming majority. The first identified review article in *Analytical Chemistry* wholly dedicated to industrial hygiene methods was in 1983,\(^{34}\) although earlier review articles (in odd-numbered years) included some industrial hygiene methods in articles discussing advances in air pollution analysis. The most recent applied review on industrial hygiene in *Analytical Chemistry*, which contains many advances in the area of chromatography applied to industrial hygiene was written by Harper et al.\(^{35}\) Review articles related to biological monitoring are not only focused on the chemical analysis of biological specimens, but also the rationale for establishing biological exposure guides. In 1975, R. Lauwers published one of the earliest reviews of biological monitoring.\(^{36}\) A more recent book, which contains 26 different chromatographic (primarily GC) methods for biological monitoring, is a useful reference for such analyses.\(^{37}\) The USEPA has also produced a compilation of methods for pesticide analysis in human (and environmental) samples.\(^{38}\) Recent *Analytical Chemistry* reviews on industrial hygiene methods currently also include a review of recently-developed biological monitoring methods.

### 3 SAMPLE COLLECTION AND PREPARATION

#### 3.1 Collection of Airborne Samples

Collection of airborne samples for chromatographic analyses takes a number of different approaches. In some cases, the contaminants of interest (gases and vapors) are collected, as found, in such devices as evacuated glass cylinders, plastic (Tedlar®, Teflon®, Mylar®, etc.) bags, electropolished stainless steel containers, or evacuated aerosol cans and then taken back to the laboratory for analysis as is, or with concentration prior to analysis using a solid sorbent, midget impinger, or cryogenic trap.\(^{39}\)

In many cases, the (gas and vapor) contaminants are concentrated in the field by drawing the air through a solid sorbent such as activated charcoal (Pittsburgh coconut-based charcoal and Columbia JXC charcoal are a couple of examples), silica gel, various synthetic polymers (such as various Chromosorbs®, Anasorbs®, Porapaks®, or XAD-2),\(^{40}\) as well as such sorbents treated with a derivatizing agent (e.g. 2,4-dinitrophenylhydrazine for aldehydes [NIOSH Method 2539], HBr for ethylene oxide [NIOSH Method 1614], or 1,2-pyridyl piperazine for certain isocyanates [NIOSH Method 5521]) and then desorbed with an appropriate solvent prior to chromatographic analysis.

In other cases, the airborne contaminant (gas, vapor, or particulate) is concentrated by trapping on a filter (e.g. glass fiber, polyvinyl chloride, cellulose ester or silver membrane), either through physical capture or else by reaction with a derivatizing agent which is impregnated in the filter. Some examples of this are the capture of MDI (methylene bisphenyl isocyanate), 4,4'-methylene diphenyl isocyanate and TDI (toluene 2,4-diisocyanate) on 1,2-pyridylpiperazine-treated glass fiber filters\(^{41}\) and the collection of PAHs in a dual collector sampling train\(^{42}\) consisting of a silver membrane filter backed up with a solid sorbent tube which traps any subliming particulate matter from the filter.

Airborne contaminants of interest to the industrial hygienist can also be concentrated by trapping by passing the air through a midget impinger or midget bubbler\(^{43}\) which contain an appropriate solvent with or without a derivatizing agent (e.g. 1,2-pyridylpiperazine for some isocyanates, 2,4-dinitrophenylhydrazine or aqueous NaHSO₃ for formaldehyde [NIOSH Methods 2539 and 2541]).

#### 3.2 Additional Preconcentration of Collected Samples

Chromatographic methods for the analysis of such samples has also been enhanced by postcollection concentration of the contaminant(s) of interest. In addition to the cryogenic or sorbent trapping of contaminants from workplace air samples, several other techniques have been used. In headspace analysis, the sample of interest (e.g. a construction material or piece of carpet suspected of emitting a compound which causes indoor air problems, a blood sample containing low levels of an airborne contaminant, or a plastic film which is heated during food packaging) is heated in a closed, inert-gas purged container and the headspace (and any volatile contaminants released from the sample) swept onto a trap which preconcentrates the sample prior to chromatographic analysis. In a related technique, an inert gas is bubbled through the liquid of interest and the gas flow trapped prior to analysis (purge and trap).\(^{44}\) As part of the sample preparation prior to analysis, certain samples that contain large amounts of interfering materials are purified
by suspending the sample of interest in an appropriate solvent and then passing the entire mixture through a solid phase, which retains the compounds of interest but allows other interferences to pass through or else be collected on a pre-filter (if undissolved). This is solid phase extraction (see below).

3.3 Collection of Biological Samples
In a number of countries, exposure standards are set on the basis of actual measurements of biological samples. Also, actual measurements of exposure, rather than surrogates such as measuring the contaminant's concentration in the "breathing zone" of the worker are sometimes preferable, if more difficult. The monitoring techniques relate to such parameters as allowable concentrations of volatile solvent contaminants, contaminant metabolites, or anesthetic gases in exhaled breath, concentration of hexachlorobenzene in blood, or concentrations of organophosphate metabolites or anesthetic gases in the urine of exposed individuals. The collection techniques for each of these analyses – which require chromatographic analysis – are varied, and require specific consideration for maintaining sample integrity and simplicity of preparation for analysis. Sample preservation prior to shipping, minimizing interferences, and other issues of quality assurance (QA) are of paramount interest.

4 GAS CHROMATOGRAPHY
In a period of less than 40 years, GC has gone from being used in a handful of industrial hygiene analytical methods to the dominant method for analysis of workplace contaminants and biological markers. As an example, of the 574 compounds or groups of compounds listed in the NMAM, 67% of them call for GC methods. Over the past 15–20 years, GC methods have evolved from utilizing packed columns to using capillary columns, both standard bore and megabore, in both split and splitless modes. Early on, temperature programming was introduced to enhance separations and speed up analyses, and the use of multiple detectors was important for compound verification until the introduction of the mass spectrometric detector for GCs about 25 years ago. An indication of the early status of the separation and detection combination of gas chromatography/mass spectrometry (GC/MS) was the appearance of a paper which was presented at an international symposium on PAHs in 1973. GC/MS is now frequently used for the identification and quantitation of volatile and semivolatile organic compounds in air. A recent example is related to pesticide usage indoors. Another recent paper using this technique focuses on the determination of microbial contamination in indoor air, a topic of considerable interest in the industrial hygiene community.

4.1 Flame Ionization Detection
The single most common detector used for the analysis of gas chromatographic eluents is the flame ionization detector (FID). Introduced in the late 1950s, FID relies upon the production and subsequent collection (in an electric field) of ions when a GC column eluent enters into an air–hydrogen flame and the molecules present are ionized. The detector is highly sensitive to compounds containing carbon–hydrogen bonds (but is responsive to other bond types as well) and is linear over many orders of magnitude of concentration. FIDs are commonly used for the detection of various hydrocarbons – aliphatic, aromatic, and alicyclic – oxygenated hydrocarbons such as alcohols, ethers, ketones, acids, aldehydes, and esters, and many chlorinated hydrocarbons. The FID is relatively rugged and is simple to maintain and operate. The variables that are used to change sensitivity include the air–hydrogen ratio in the flame and the flow rate through the flame. Collection voltage typically remains constant. NIOSH has a number of GC methods which call for the use of a FID, including those for various aromatic hydrocarbons (NIOSH Method 1501), aliphatic hydrocarbons (NIOSH Method 1500), chlorinated hydrocarbons (NIOSH Method 1003), ketones (NIOSH Method 1300), and alcohols (NIOSH Methods 1400–1403). Although not as sensitive as some detectors, for certain compounds, the linearity of response of FIDs over many orders of magnitude makes them a highly desirable detector for gas chromatographic analyses. An example of the application of gas chromatography/flame ionization detection (GC/FID) is a paper by Wellson, et al. reporting on monitoring for glutaraldehyde, a disinfectant and preservative used as a formaldehyde replacement. Cresols and phenol are common analytes measured in the urine as measures of exposure to toluene, and benzene and phenol, respectively, and a method for their determination using GC/FID was published by Needham et al. in 1984. Expired air measurements using GC/FID was reported by Guillemain and Guberan.

4.2 Electron Capture Detection
Electron capture detection (ECD), which relies on the attenuation by electronegative atoms of a beta-particle beam from a radioactive source (e.g. $^{60}$Ni, $^{3}$H) within the detector, has been developed and improved within the past 25 years. It is very effective for the detection of compounds containing halogen atoms, which has made
it extremely useful for the detection of halogenated compounds such as dichlorodiphenyltrichloroethane (DDT), 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), Lindane, Chlordane, polychlorinated biphenyls (PCBs), and polybrominated biphenyls (PBBs). Human exposure to these compounds, whether in a field sample, in a residence, or in a workplace can now be determined with considerable sensitivity. For example, the analysis of PBBs in blood serum using gas chromatography/electron capture detection (GC/ECD) was reported in 1980 by Burse et al. Another example of the use of GC/ECD is a recently reported method developed for assessing occupational exposure to two compounds used as taggants in plastic explosives.

Another analytical application in the area of biomonitoring is discussed in a recent paper on the biological monitoring of workers for 4,4'-methylenebis(2-chloroaniline) using GC/ECD.

4.3 Mass Spectrometric Detection

In the mid-1960s, in order to enhance the ability to unambiguously identify compounds eluted from a GC column, mass spectrometers were interfaced with the effluent from GC columns. The critical feature of the mass spectrometric detectors used was that they were quadrupole detectors, rather than magnetic sector detectors, which allowed one to do a scan of mass to charge ratios from 28 to 300 within a second, allowing one to look at a whole range of ion fragments within the time duration of a capillary GC peak. The mass spectral fingerprint gave more reliable information than retention time alone, about the compound being eluted. The development of high-speed computers allowed the resulting mass spectra to be matched against large libraries of known mass spectra, using various algorithms, and assigned a “matching index” which indicated the degree of correspondence between the unknown peak’s mass spectrum and the library spectrum. EPA (Environmental Protection Agency) Methods TO-2 and TO-13 are particular approaches for using GC/MS to identify and quantitate a large array of organic compounds that might be found in indoor or ambient air. One can also use the mass selective detector to monitor a single ion (selective ion monitoring, (SIM)), if one knows what compound/ion to expect, considerably enhancing the sensitivity of this detection method and reaching into the picogram range for limits of detection (LOD). A method for derivatization and GC analysis of formaldehyde using GC/MS using SIM has been reported by Wu and Que Hee.

The GC/MS technique is also a powerful one in the identification of unaltered compounds or metabolites in biological specimens.

4.4 Fourier Transform Infrared Spectroscopic Detection

The development of FTIR detectors (see Gas Chromatography/Infrared Spectroscopy), which can perform a scan of infrared absorption over a range of ~800 to 350 cm⁻¹ in a few seconds, has allowed this technique to also do a number of scans during the duration of even a highly resolved capillary GC peak. As with MS detectors, the ability to store vast libraries of infrared spectra in a high-speed computer’s memory allows one to match the FTIR spectrum of an unknown against those in the library, with the creation of similar “matching indices”. A paper by Wieboldt et al. discusses the use of FTIR in the analysis of certain pyrethrin pesticides, compounds included in the NMAM.

4.5 Other Gas Chromatographic Detectors

Flame photometric detection (FPD) has gained widespread use for industrial hygiene analyses because of its sensitivity and selectivity to sulfur and phosphorus in the compounds of interest. These flame emission detectors are used for the detection of low concentrations of organosulfur compounds in workplace air (e.g. hydrogen sulfide, mercaptans, and organo-sulfides and -disulfides) and for the detection of metabolites of organophosphate phosphates, such as dimethyl- and diethyl-phosphates and in urine. Detection levels at the nanogram level allow measurement of low-level exposure to such compounds. Another example, a paper by Kennedy et al. describes a method for the simultaneous determination of 19 organophosphate pesticides in air using GC and a flame photometric detector. FPD has also been used for GC effluent in the separation of organogermanium and organotin compounds.

Hall (electrolytic) conductivity detectors operate by running the organic eluates from a GC column through a high-temperature reactor, which decomposes them to carbon dioxide and small inorganic molecules (the latter, if the molecules contain N, S, or a halogen atom), and then runs the decomposition products through an electrolytic conductivity cell. Changes in the conductivity are a measure of the concentration of the compound of interest in the effluent. The Hall conductivity detector is typically used for pesticide and herbicide analyses and is useful in assessing workplace exposures to such compounds. A couple of examples of such applications of Hall detectors with GC are found in Lawrence and McLeod and Stetten et al.

Argon ionization detectors have been used in at least one transportable GC sold to the industrial hygiene community (Sentrex Systems, Inc., Ridgefield, NJ.). This detector relies on the use of argon atoms, excited to a neutral, energetic state by a radioactive source, transferring their excitation energy to organic molecules.
and, as a result, ionizing them. The ionized molecules are then measured in a manner similar to that for flame ionization. The advantage of an argon ionization detector is that no flame is needed, thus eliminating the need for fuel and oxidant gases, and reducing the weight of the instrument.

Photoionization detectors (PID) rely on the detection of species being eluted from a GC column by their ionization by ultraviolet (UV) light. UV lamps with energies ranging from 8.3 to 11.7 eV are currently available (not all lamp energies are available for all instruments), and gas chromatographs with PIDs can be purchased from several manufacturers of such instruments. An article by Driscoll and Clarici gives a good overview of PIDs and their possible use in industrial hygiene chromatography. The thermionic ionization detectors, sometimes called nitrogen–phosphorus detectors, are GC detectors which can be particularly sensitive to N and P under the right conditions. They typically cause ionization of the compound(s) of interest through surface ionization processes in the presence of a low-work-function alkali-metal-containing bead, with subsequent ion collection and measurement. Depending on the gaseous boundary around the detector and the geometry of the detector, they can be made highly specific for nitrogen- and phosphorus-containing compounds or for other families of compounds. An example of this detection is found in a paper by Skarping et al. Another application of a thermionic detector with GC is the measurement of low concentrations of phosphine in workplace air, as reported by Vinsjansen and Thrane.

Compounds containing metals atoms have also been chromatographed, using graphite furnace atomic absorption spectrophotometry as the detector. In a paper by Robinson et al. trapped alkyl lead compounds were chromatographed and the column effluent connected directly into the graphite furnace atomizer for lead quantitation.

### 4.6 High-speed Gas Chromatography

Opportunities for improving the productivity of the GC technique lie in the reduction of the separation time for compounds of interest to industrial hygienists. A number of developments in this area have been made through which the separation time can be reduced significantly. Sandri reviews developments in fast capillary GC relevant to industrial hygiene. As an example, he shows a mixture of ten aliphatic and aromatic hydrocarbons which can be separated (m- and p-xylene are unresolved) in about 150 s. This is accomplished by reducing film thickness inside the capillary to 0.25 µm, while a chromatogram for the same compounds using a 3 µm film thickness has a retention time of about five times longer. Compounds which elute prior to benzene required the thicker film to resolve them. A commercially available system which claims separation times ten times shorter than regular GC uses a patented cryofocusing inlet system, short column lengths, and high carrier-gas velocities to achieve much-shortened retention times. A complete chromatogram—with nearly baseline separation—of 24 volatile organic compounds commonly found in the workplace is generated in about 135 s.

### 4.7 Gas Chromatography Used in Portable, Direct-reading Instruments

Starting in the early 1980s, manufacturers have begun to build portable, or at least transportable, GCs for use in the field as direct-reading instruments. Initially quite heavy and bulky because of the the necessary weight of batteries, carrier and flame gases, and thermal isolation of the GC column, as well as the size of the column and associated electronics, these instruments are now found in truly hand-held devices. Part of that development has come from batteries with higher energy densities, lighter-weight detectors, and the development of GC columns that are extremely small and have been etched on silicon wafers on the order of 25 cm².

A recent addition to the portable GC market employs a surface acoustic wave (SAW) detector rather than FIDs or PIDs more commonly found in such devices. The SAW detector relies on the measurement of the change in (radio)frequency of mechanical waves on the surface of a piezoelectric substrate. The frequency changes as a function of mass adsorbed on its surface due to the presence of an adsorptive coating on the surface of the detector. These devices are being marketed as nearly real-time measurements of workplace and ambient air, are quite simple, as well as rugged and will certainly see wider use in the next decade, perhaps more often in multisensor arrays.

### 4.8 Compilation of Gas Chromatographic Analytical Methods

Table 1 gives a summary of GC methods which have been validated by one of six sources (NIOSH, OSHA, USEPA, Intersociety Committee, ASTM, or the HSE) for the measurement of contaminants in airborne, surface wipe, or biological specimens.

### 4.9 Micro Gas Chromatography

The rapid development of micromachining techniques has had its influence on GC related to occupational hygiene. Capillary GC columns 9 m long, with dimensions of 300 µm wide by 10 µm high, along with similar dimensions for the detectors, have been fabricated by

(continued overleaf)
micromachining. An excellent review article by Manz, et al. discusses these issues, and an overview article by Marshall gives some idea of what lies ahead with regard to microchromatography, both with regard to columns and detectors. These developments begin to make possible truly hand-held GC, which have become available, and will certainly be common in the not-too-distant future.

5 HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY

The development of HPLC for the separation of non-volatile or low-volatility organic compounds led to the rapid application of such methods for industrial hygiene monitoring. One of the earliest uses of this technique was in the separation and analysis of PAHs, which can also be analyzed using gas chromatographic methods. The sensitivity of detection for many of the PAHs by using a fluorescence detector in combination with liquid chromatographic separation has proved to be highly desirable, in view of the carcinogenicity of a number of PAHs. More recent developments which utilize HPLC include the analysis of isocyanate derivatives formed when the airborne isocyanate is derivatized by contact in an impinger or on a glass fiber filter, with 2-pyridyl piperazine or several other common derivatizing agents. The analysis is commonly done using either UV or fluorescence detection. A number of airborne aldehydes are commonly derivatized with 2,4-dinitrophenylhydrazine (typically in a solvent in an impinger, or coated on a solid substrate in a sorbent tube) and the derivatives analyzed using HPLC.

5.1 Ultraviolet/Visible Radiation Detection

UV/VIS light detection of HPLC effluents is a very common technique which has gained widespread use in industrial hygiene applications of this chromatographic technique. A method for the simultaneous analysis of organonitrogen pesticides is a good example. Another common use of the technique and detector is for the analysis of isocyanate derivatives prepared in the course of measuring a variety of isocyanates in workplace air. In the area of biological monitoring Sanderson et al. have reported on an analytical method for the determination of metabolites of the herbicide alachlor in urine using HPLC with UV detection as one of the analytical methods. Another biomonitoring application of HPLC with UV related to isocyanates has been published by Dalene et al.

5.2 Fluorescence Detection

HPLC with a fluorescence detector has been used for the determination of exposure of workers to PAHs during aluminum smelting as reported by Ny et al. The monitoring was based on the analysis of 1-hydroxypyrene as a marker for PAH exposure, which was reported elsewhere. In seeking to identify a single method for workplace air analysis of a variety of isocyanates, Streicher et al. have used both fluorescence and UV detectors to analyze a number of different isocyanate derivatives in order to determine total isocyanates (including nonmonomers) in an air sample. Using four different derivatizing agents, 1-(9-anthracenylmethyl) piperazine (MAP), 1-(2-methoxyphenyl) piperazine (MOPP), 9-(methylaminomethyl)anthracene (MAMA) and TRYP, HPLC separation of the derivatives and quantitation using both methods was done using phenyl isocyanate, 1,6-hexamethylene disiocyanate, TDI MDI and butyl isocyanate. An interesting application for a high speed HPLC analysis of a complex mixture of PAHs using fluorescence detection was reported by Dong et al.

5.3 Mass Spectrometric Detection

For those situations in which traditional detection alone was not satisfactory for the identification and quantitation
of compounds being analyzed in industrial hygiene samples, mass spectral detectors were developed which would enable the analyst to identify the eluted compound by its fragmentation pattern-matched against a library of fragmentation patterns stored in the memory of a computer. Three different methods of introducing the eluted sample into the mass spectrometer have been commercialized: moving belt interface, direct liquid injection, and thermospray. These are discussed elsewhere in detail (see Liquid Chromatography/Mass Spectrometry). Liquid chromatography/mass spectrometry (LC/MS) has been used in the analysis of chlorinated herbicides which is useful in the identification of indoor air contamination in residences which had historically or unintentionally been treated with such compounds.\(^{(84)}\) It has also been used in biomonitoring for exposure to a series of phenolic compounds.\(^{(85)}\) A method that combines HPLC and MS, along with GC for the quantitation of PAHs in air particulates, of considerable interest to industrial hygienists in coal gasification and liquefaction and coking operations, was reported by Wise et al.\(^{(86)}\)

### 5.4 Atomic Absorption Spectrometry

A technique which is used with some frequency combines HPLC with an atomic absorption analysis. The compounds of interest are separated by HPLC and then analyzed, on a continuous basis, by an atomic absorption technique (see Flame and Vapor Generation Atomic Absorption Spectrometry and Graphite Furnace Atomic Absorption Spectrometry), either flame or flameless. An example of this is the separation of arsenic-containing species in urine using HPLC and analysis using hydride-generation atomic absorption spectrometry (AAS) for analysis.\(^{(87)}\)

#### 5.5 Inductively Coupled Plasma Spectroscopy

Another technique reported in the literature combines HPLC with ICP (inductively coupled plasma) spectroscopy. In this case, HPLC is used to separate Cr(III) and Cr(VI), of considerable interest to industrial hygienists, and then ICP is used to quantitate chromium in each of the two oxidation states.\(^{(88)}\)

### 5.6 Table of Methods

Table 2 summarizes HPLC methods found for airborne, surface, or biological contaminants from six different references.

#### 6 ION CHROMATOGRAPHY

The development by Small et al.\(^{(14)}\) of IC led to widespread use of this technique in industrial hygiene.

\( ^a \) NIOSH Manual of Analytical Methods.\(^{21}\)

\( ^b \) OSHA Analytical Methods.\(^{22}\)

\( ^c \) Other Methods: EPA TO-Methods.\(^{23}\) MASA.\(^{26}\) MDHS: HSE, Methods for the Determination of Hazardous Substances.\(^{28}\) ASTM: 1997 Annual Book of ASTM Standards; section 11.\(^{25}\)

Detectors for IC column effluents now include those based on the absorption of UV/VIS light, amperometry, fluorescence, flame emission, radioactivity, atomic absorption, and ICP spectroscopy. IC has allowed the individual determination of a mixture of airborne inorganic acids (NIOSH 7903) instead of together, as had been previously done using titrimetric methods. IC has been used, in conjunction with cold vapor AAS to speciate a mixture of arsenic-containing compounds, which are used as herbicides, pesticides, and wood preservatives.\(^{89}\) Abuk et al.\(^{90}\) described the analysis of bromide ions in biological fluids using IC with amperometric quantitation. A paper by Lorberau\(^{91}\) described a method for the determination of both gaseous and particulate fluorides using IC. MASA\(^{26}\) has an entire section (pp. 230–242) on IC applied to air monitoring. Table 3 shows IC methods found in NMAM, OSHA, and other common references.

7 OTHER CHROMATOGRAPHIC TECHNIQUES WITH PRESENT AND FUTURE INDUSTRIAL HEALTH APPLICATIONS

7.1 Supercritical Fluid Chromatography

The technique of supercritical fluid chromatography (SFC) has been described in detail elsewhere (see Supercritical Fluid Chromatography) and has application in industrial hygiene in the assessment of occupational exposure by means of biological monitoring. Although one author commented that SFC bridges the gap between GC and liquid chromatography (LC) and offers a feasible alternative for the analysis of PAHs, there has not been a lot of method development of this technique related to industrial hygiene. There are some early applications of SFC\(^{92,93}\) which is of interest to industrial hygienists. In contrast to air sample analysis, biological samples are quite complex chemically and require much more...

a NIOSH Manual of Analytical Methods.(21)

b MASA.(20) ASTM: 1997 Annual Book of ASTM Standards; section 11.(25)

7.2 Supercritical Fluid Chromatography and Fourier Transform Infrared

Although not frequently used for industrial hygiene monitoring, SFC using FTIR spectrophotometry was identified as a method for pesticide monitoring – relevant in agricultural workplaces. The method involved the separation and quantitation of aldicarb®, methomyl, captan, and phenmedipham.(96) SFC has also been applied to the separation and quantitation of PAHs.(97)

7.3 Thin-layer Chromatography

Although infrequently used for industrial hygiene analyses, there is an entire method devoted to such analyses using this technique. Method 102B of MASA: “Separation and Microanalysis of Airborne Particulate Matter for Benzo[a]pyrene using Thin Layer Chromatography and Spectrofluorimetry”,(26) Chapter 22 (pp. 127–130) of MASA(26) addresses the application of TLC to air monitoring. Another possibility of increasing interest to industrial hygienists is the analysis of mycotoxins in air, related to both indoor and agricultural settings, and a paper by Ripphahn and Halsaap(98) describes the use of high-performance TLC to separate some aflatoxins. TLC has been commonly replaced by either GC or HPLC methods for this compound.
8 QUALITY ASSURANCE AND CHROMATOGRAPHIC TECHNIQUES

8.1 Requirements for Method Validation
As new chromatographic methods are developed for industrial hygiene-related monitoring, they must be validated, i.e. evaluated to assure that they are reproducible, accurate and precise, and that any interferences or confounders are identified. To that end, NIOSH has defined several protocols for such method validations. One such validation is intended for solid sorbent tubes, using a pump to draw air through the tubes. Another one is intended for the use of diffusional (passive) monitors, in which the airborne contaminant (vapor or gas) diffuses to the sampling device as described in Fick’s Laws of Diffusion. The parameters that are generally evaluated in validating a method are trapping efficiency, desorption recovery, sampling rate, sampling volume, storage stability (both with regard to time and temperature), and interferences. For passive monitors, an experimental determination of sampling rate, air velocity and monitor orientation effects, as well as sorbent saturation mass, are also determined.

8.2 Acceptability Criteria
NIOSH has developed criteria for acceptability of industrial hygiene analytical methods. The most generally applied is that the accuracy of the method as described in the reference is ≤25%. In addition, NIOSH does not consider a method to be acceptable if recovery of the contaminant from the trapping medium is ≤75%, and methods with recoveries of >10% after 7 days of storage are considered to be suspect.

8.3 Internal Compared with External Standards
By internal standards are meant compounds similar to the analytes sought by the chromatographic analysis, which are added in known amount at the outset of the analysis to the sample being analyzed, and serve as an indicator of the overall recovery of the analytical method. When internal standards are used, then the results are corrected for any diminution of the internal standard, compared to internal standard analyzed directly in the solvent used, without processing. External standards are standards of the unknown material which are analyzed separately to determine the instrument detector’s response, i.e. to create a calibration curve. External standards and separately determined recoveries are used in conjunction to determine the level of analyte in the sample being analyzed.

9 ALTERNATIVES TO CHROMATOGRAPHIC TECHNIQUES
The sheer number of chromatographic methods that have been developed and validated for workplace and biological contaminants suggests that it would be difficult, if not impossible to replace them entirely. The power of chromatographic methods to separate and quantitate mixtures of organic compounds in an airborne or biological specimen is unmatched. In those cases in which a single, known compound is found in such samples, and chromatographic separation is not needed, then a few methods exist for the quantitation of such compounds. Direct MS, without chromatographic separation might be applicable in a few cases. The same might be true when using detectors such as PID, FID, and ECD. Often, such detectors are used, without chromatographic separation, in direct reading instruments which are used in a mono-contaminant environment or as leak detectors or as indicators of qualitative levels of contamination.

In a few cases, non-chromatographic methods have been developed which are compound specific. As an example, NIOSH developed a polarographic method for the quantitation of formaldehyde, which appeared in NMAM but also appeared in the literature as a paper by Septon and Ku.

ACKNOWLEDGMENTS
The author would like to thank those colleagues, past and present, from the University of Iowa Hygienic Laboratory, The Dow Chemical Company Corporate Industrial Hygiene Group, and the University of Washington Department of Environmental Health for helping me mature into an industrial hygiene chemist over the past 24 years.

Cyclic activation analysis (CAA) is a method of activation analysis for elemental analysis, in which a sample is irradiated, decayed, counted, and then irradiated again. This process is repeated for a number of cycles, and the spectra from each counting are summed together to give one final total spectrum. By this process, the counts of a short-lived nuclide of interest are considerably increased, and the analytical sensitivity of elements is significantly improved. The most commonly used CAA is the cyclic neutron activation analysis (CNAAn) by irradiation with the thermal, epithermal, and fast neutrons produced from nuclear reactor, accelerator, and isotopic neutron source. The nuclear reactor can supply a much high neutron flux and is most often used for this purpose. At least 20 elements produced short-lived nuclides (half-life <100 s) by thermal neutron bombardment, and more than 10 elements produced nuclides with half-life of 100–600 s. These can be determined by thermal and epithermal neutron CAA. This technique has been widely applied in biological, environmental, geological, and industrial studies, and most often measured elements include Se, F, Pb, Hf, Sc, O, Ag, and Rh.

The advantages of CAA, as compared with conventional activation analysis, include significant improvement in the detection limit, analytical precision, and accuracy for the elements by using short-lived nuclides; short experimental time and increased analytical number of samples per unit time; capability of estimation or confirmation of the half-life of the short-lived nuclide; and determination of the degree of homogeneity of a sample. However, the application of CAA is limited by the number of elements determined, because only some of the elements determined by conventional activation analysis can be determined by this method. In addition, dead time and pileup are serious problems in CAA and must be corrected. The principle, selection of optimal experiment conditions, detection limit, analytical precision of CAA, as well as the dead time and pileup corrections are discussed in this article. Some applications of this method are highlighted.

1 INTRODUCTION

Activation analysis has been well documented as a powerful technique for elemental analysis (see Instrumental Neutron Activation Analysis, Charged Particle Activation Analysis). Its high sensitivity and accuracy, simultaneous multielement analytical capability, and matrix-free and nondestructive analysis make it wide applicable in a variety of research fields such as biological, environmental, geological, industrial, archeological, and forensic studies. Of all kinds of activation analyses, reactor neutron activation has been the mostly used, and as many as 70 elements can be easily determined. However, for many elements, an analytical period from days to weeks is needed because the nuclides detected, which are produced by reaction of their stable isotope with neutron, have longer half-life, such as $^{75}$Se (120 days), $^{46}$Sc (84 days), $^{112m}$Ag (250 days), and $^{181}$Hf (45 days). To attain the required sensitivity, a long-time irradiation, delay, and counting are necessary. This reduces its competitive capability to other analytical techniques, such as inductively coupled plasma mass spectrometry (ICP–MS). The use of the short-lived nuclides of element in preference to their longer-lived activation products can significantly reduce the total experimental time, which in turn can reduce the analytical period and increase the number of samples measured per day, and make activation analysis more cost-effective and competitive. On the other hand, several elements can be determined...
by neutron activation analysis (NAA) only through the measurement of short-lived nuclide, such as $^{20}$F (11 s), $^{16}$O (27 s), and $^{207m}$Pb (0.8 s). Therefore, NAA using short-lived nuclides has been given more attention.

The saturation activation of short-lived radionuclides is reached quickly on irradiation, and there is no further increase in activity with time. Similarly, the counting is also limited by half-life since the activity of a short-lived radionuclide decays very quickly, and further counting cannot accumulate any more counts of radionuclides of interest; on the contrary, it increases the background derived from long-lived interfering nuclides. In addition, owing to the short half-life, the number of radioactive nuclei ($N^*$) formed in saturation is small ($N^* = N\sigma\Phi/\lambda = N\sigma\Phi t_{1/2}/\ln 2$, where $N$ is the number of target nuclei, $\sigma$ is the activation cross section, $\Phi$ is the neutron flux, $\lambda$ is the decay constant, and $t_{1/2}$ the half-life of the formed radioactive nuclide). Consequently, the counting has a large statistical error, and both the analytical accuracy and detection limit are unsatisfied. It is possible, however, to overcome this by reirradiating sample and counting it again, once the initial activity has been decayed away. The number of counts of the nuclide of interest can be significantly increased by repeating this process of irradiation-decay-counting-decay and irradiation again for a number of cycles, i.e. cyclic activation, and summing the spectra from each counting to give a final spectrum. By this CAA, the sensitivity, precision, and accuracy will be considerably improved.

The history of CAA can be traced back to the beginning of 1960s. In 1960 and 1961, Anders first reported a technique where a sample is cycled between the irradiating source and the radiation detector, in order to improve both the sensitivity and statistical certainty of the elemental analysis. In his experiment, he repeatedly irradiated the sample with neutrons from a Be target of a 2-MeV Van de Graff accelerator and counted on a NaI(Tl) detector for two consecutive periods of equal length. By subtracting the spectra acquired from each other, the resulting $\gamma$-ray difference spectrum represented the contribution from only very short-lived nuclides and suppressed the contribution of longer-lived components in the $\gamma$-spectra of the activated sample. The method was documented by determining fluorine using faster neutron reaction of $^{19}$F($n,\alpha$)$^{16}$N, and Se, Ag, Hf, F, and O by thermal neutron ($n,\gamma$) reactions. Preliminary investigation indicated the usefulness of the technique for the determination of 18 elements, such as O, F, Na, Sc, Ge, Se, Br, Y, Rb, Rh, Ag, In, Er, Hf, W, Yb, Ir, and Au. However, the term cyclic activation analysis is not mentioned in this article. In 1966, Caldwell et al. suggested the use of a similar technique as part of a combination neutron experiment for remote elemental analysis. The term cyclic activation analysis was first used by Givens et al. in 1968, when they measured $^{16}$N and $^{24m}$Na using a technique similar to that of Anders. However, the irradiating source, rather than the sample, was cycled electronically. Using this facility, the nuclides with half-life down to a few milliseconds, such as $^{24m}$Na(20 ms), can be utilized for analytical purposes. In 1969, Tani et al. used a similar experimental facility to observe the $\gamma$-spectra of $^{205}$Pb (∼4 ms) and $^{207m}$Pb (800 ms).

In order to obtain the high sensitivity required while using CNAA as a useful trace element analysis technique, Ozek and Spyrou et al., in 1973, first used nuclear reactor as a neutron source to supply a neutron flux more than three orders of magnitude higher than other sources used by the earlier workers, such as an accelerator and isotope sources for CNAA. They published their results on the measurement of lead through $^{207m}$Pb in environmental samples. Since 1970s, many facilities for CAA have been set up, and methodology and application studies were carried out. This article is an updated version of the previous one published in the first edition of this book in 2000.

2 THEORY

2.1 Equation of Cyclic Activation Analysis

The principle of CAA has been described by Given et al. and Spyrou. In this method, the sample is irradiated for a short period of time, and after a delay period from the end of irradiation, the radiation emitted is counted for a short period of time, then the sample is irradiated again and the entire process is repeated for a number of cycles (Figure 1). The detected radiations at each counting period are summed and finally a total cumulative detector response is obtained. The cycle period $T$ is given by Equation (1):

$$ T = t_i + t_d + t_c + t_w \quad (1) $$

where $t_i$ is the time of irradiation, $t_d$ is the delay time, i.e. the time between the end of irradiation and the start of counting, which is usually the time required to transfer the sample from the irradiation position to the counting station, or to transfer the irradiation source to the sample station, $t_c$ is the counting time, and $t_w$ is the waiting time, i.e. the time between the end of counting and the start of the next irradiation.

The detector response (or the number of counts) for the first cycle is given by Equation (2):

$$ D_1 = \frac{N\sigma\Phi T}{\lambda} (1 - e^{-\lambda t_i}) e^{-\lambda t_d} (1 - e^{-\lambda t_c}) \quad (2) $$
where the definitions of $\sigma$, $\Phi$, and $\lambda$ are the same as above, $I$ is the intensity of the radiation of interest, and $\varepsilon$ is the counting efficiency of the detector.

In the second counting period, the detector response is the same number of counts due to the second irradiation, in addition to what was left from the first irradiation, the same number of counts due to the second irradiation, the counting efficiency of the detector.

Equation (4)

$D_n = D_1 (1 + e^{-\lambda T} + e^{-2\lambda T} + e^{-3\lambda T} + \cdots + e^{-(n-1)\lambda T})$

Similarly, for the $n$th cycle, which can be expressed by Equation (4)

Equation (5) gives the basic relationship for CAA.

$D_c = \frac{N\Phi\sigma \varepsilon}{\lambda} \left[ \frac{n}{1 - e^{-\lambda t_d}} - \frac{e^{-\lambda t_d}(1 - e^{-n\lambda T})}{(1 - e^{-\lambda T})^2} \right] \times (1 - e^{-\lambda t_c})e^{-\lambda t_d}(1 - e^{-\lambda t_c})$

2.2 Selection of Time Parameters

The detector response may be maximized by a proper selection of the parameters in Equation (5). For a given total experiment time, $T_i$ ($T_i = nT = mt_{1/2}$), the maximal value of $D_c$ occurs when $t_d = t_w = 0$ and $t_i = t_c$. However, the fact is that $t_d$ and $t_w$ are not zero and their values ultimately depend on the transfer system used. When the transfer is done manually, the transfer time can be relatively long in the value of 10 s to 1 min; in this case, the method sometimes is referred to as pseudocyclic activation analysis (PCAA). In some fast transfer systems, where the transfer is completed electronically and through computer control, the transfer time is of the order of 0.1 s and less. The transfer time can be made very small when there is no physical transfer of the sample but a pulsed irradiation is used, which was suggested as the "real" CAA. For the following discussion, unless otherwise stated, it is assumed that $t_d = t_w = 0$ and $t_i = t_c$.

Figure 2 shows the variation of detector response for the nuclides of interest with the total experimental time ($T_i = mt_{1/2} = nT$) in conventional and cyclic case with different cyclic numbers. It is clear that below a certain experimental time, conventional activation is to be preferred to cyclic activation, and the cross over point of curves between conventional and cyclic activation shifts to longer experimental time with an increasing number of cycles. After the cross over point, cyclic activation has a higher detector response than that of conventional one-shot irradiation. For a certain total experimental time, such as $T_i = 10t_{1/2}$, the cumulative detector response increases with increasing number of cycles in the beginning, and there is an optimum cyclic number, after which the detector response does not increase and slowly decreases (Figure 3). Figure 3 shows the variation of the conventional and cumulative signal with total experiment time, $t_d = t_w = 0$, $t_i = t_c$ and $n$ is the number of cycles.
with increase in the total experiment time in the beginning and 95% of saturation activity is obtained before 5\(t_{1/2}\), following which a further increase in the total experiment time becomes insignificant (Figure 2). However, for CAA, this time point becomes longer. For \(n = 4\), 95% of saturation activity is obtained after 15\(t_{1/2}\), and for \(n = 12\), after a total experiment time of 50\(t_{1/2}\), the activity still increases with the increase in total experiment time.

However in CAA, the radionuclides produced from elements in the matrix, which has a longer half-life than the nuclide of interest, will decay slowly between irradiations and therefore the underlying background will increase through successive irradiation. Consequently, the detection of an element does not depend solely on the signal from the nuclide of interest, but also depends on the background contribution from the matrix elements.

The purpose of CAA is to improve the analytical precision and detection limit for the elements of interest. The analytical precision is usually expressed by relative standard deviation of a signal \(S\) measured above a background \(B\) (Equation 6):

\[
\delta = \frac{\sqrt{S + 2B}}{S} \tag{6}
\]

For the cumulative spectrum of \(n\) cycles, it is expressed as Equation (7):

\[
\delta_n = \sqrt{\frac{(sD_c + 2bD_c)}{sD_c}} \tag{7}
\]

where \(sD_c\) is the cumulative detector response for the nuclide of interest, \(sD_c\) is the cumulative detector response for the nuclide making the major background contribution to the signal from the nuclide of interest.

The detection limit \(L_d\) is usually given by Equation (8):

\[
L_d = 2\sqrt{B} \quad \text{(counts)}
\]

or

\[
L_d = \frac{2\sqrt{B}}{S/m} = \frac{2m\sqrt{B}}{S} \quad \text{(µg)} \tag{8}
\]

where \(S/m\) is the counts per unit mass element of interest.

For CAA with \(n\) cycles, the detection limit is given by Equation (9):

\[
L_d = \frac{2\sqrt{bD_c}}{sD_c/m} + \frac{2m\sqrt{bD_c}}{sD_c} \tag{9}
\]

Therefore, \((\sqrt{sD_c}/\sqrt{D_c})\) or \((D_c/\sqrt{sD_c})\) and \((\sqrt{bD_c}/\sqrt{sD_c})\) or \((D_c/\sqrt{bD_c})\), not the detector response for the nuclide of interest, must be optimized, when the most suitable cyclic timing parameters are chosen for a nuclide.

In Figures 4 and 5, the signal-to-noise ratio \((sD_c/\sqrt{D_c})\), and the ratio of signal to the square root of sum of \(sD_c\) and \(2bD_c\), \((sD_c/\sqrt{sD_c + 2bD_c})\), are plotted versus total experiment time \((nt_{1/2})\) for comparison of cyclic with conventional activation analysis. In this case, for illustrative purpose, assuming that only one long-lived nuclide with a half-life \((T_{1/2})\) of 10 times half-life of nuclide of interest \((T_{1/2} = 10t_{1/2})\) is considered to contribute to the underlying background of the signal. It can be seen that the background plays a significant role in emphasizing the difference between conventional and cyclic cases. With increase in the total experiment time, \((sD_c/\sqrt{sD_c})\) and \((sD_c/\sqrt{sD_c + 2bD_c})\) have a maximum and this maximum shift to a longer experimental time with increasing number of cycles (Figures 4 and 5). Comparing with Figure 2, the cross over point between conventional and cyclic activation in Figure 4 is shifted to a lower value of \(m\),...
i.e. cyclic activation becomes advantageous for shorter total experiment time than the case just considering the detector response.

Figure 5 shows the variation of signal-to-noise with the total experimental time (number of cycle) under a certain cycle period \((T_{1/2} = 10T_{1/2})\). It is clear that in this case, signal-to-noise ratio increases always with increasing total experiment time.

To obtain a better cyclic advantage factor over conventional activation, it is obvious that one must increase the total experiment time \(nT_{1/2}\). Choice of the best total experiment time for cyclic activation is therefore a compromise between the time available for sample analysis and the detection limit to be achieved. Whenever the total experiment time is chosen, the number of cycles \(n\) or cycle period, \(T = T_{1/2}/n\), has to be decided. In Figure 3, the variation of the signal \((D_c)\) and the signal-to-noise ratio \((D_c/\sqrt{sD_c})\) were plotted as a function of the number of cycles \(n = T_{1/2}/T\). It can be seen that after a certain cycle, \((D_c/\sqrt{sD_c})\) and \(sD_c/\sqrt{bD_c})\) increase very slowly, and with further increase in the number of cycles these become insignificant. After a maximum occurs, \(sD_c/\sqrt{bD_c})\) decrease slowly. For example, if \(T = 10T_{1/2}\) and \(T_{1/2} = 10T_{1/2}\), 95% of saturation activity of nuclides can be obtained after four cycles and 95% of a maximum of \((D_c/\sqrt{sD_c})\) after eight cycles. In addition, in order to maximize signal \((D_c)\), the optimal number of cycles is always smaller than that required for maximizing the signal-to-noise ratio \((D_c/\sqrt{sD_c})\), and it also increases with the increase in the half-life of the background for the same total experiment time. However, it becomes less pronounced for the half-life of the background more than 100\(T_{1/2}\).

Spyrou et al., and Spyrou and Kerr investigated the effect of the transfer time \(t_d\) and \(t_w\) on \((D_c)\) and \((D_c/\sqrt{sD_c})\), they found that the cross over point between cyclic and conventional activation was shifted to a longer experiment time with increasing transfer time. It means that CAA becomes more preferable to the conventional method with decreasing transfer time, and the transfer time is an important factor effecting the detection limit and precision.

In real situation, many long-lived nuclides from matrix elements, not just one, will contribute to the underlying background of the peak of the nuclide of interest after activation. For calculating these contributions and optimizing the parameters of cyclic activation, many computer programs have been developed. In Tout and Chatt’s program, \((sD_c/\sqrt{bD_c})\) and \((D_c/\sqrt{sD_c})\) for nuclides with half-lives shorter than 90% of maximal \((D_c/\sqrt{sD_c})\) can be calculated for individual matrix elements and the total background. The optimal irradiation and counting time (or number of cycles) and its ranges were finally given for maximum and 95% of maximum of \((D_c/\sqrt{sD_c})\). Their results indicated that a single value of \(t_d\) and \(t_w\) can be used to produce results close to the maximal \((D_c/\sqrt{sD_c})\) for nuclides with a large range of half-lives, i.e. for a total experiment time of 5 min, \(t_d = t_w = 6–7\) s will produce values of more than 90% of maximal \((D_c/\sqrt{sD_c})\) for nuclides with half-lives in the ranges 3–22 s. This means that a number of short-lived nuclides can be measured at close to their best detection limits by using only one set of CAA.

In Al-Mugrabi and Spyrou’s program, besides the contribution from the photopeaks of nuclides produced by matrix elements to the background, the Compton continuum, single and double escape peaks, and bremsstrahlung were also considered. By entering the information in Tout and Chatt’s program, as well as by entering neutron flux, mass of sample and nuclear data of nuclide of interest and detector parameters, not only the optimized activation conditions were produced but also simulated \(\gamma\)-spectrum, detection limits, and precision for the elements of interest were presented.
Figure 7 shows the experimentally measured variation of detection limit and analytical precision of CNAA for Se in human hair, with cyclic period of $T = t_1 + t_3 + t_5 + t_7 = 30 + 3 + 30 + 3 = 66$ s. It can be clearly seen that CNAA can significantly improve the detection limit and precision.

2.3 Estimation or Confirmation of the Half-life of Nuclide

Another function of CAA, estimation and confirmation of the half-life of nuclide by using the data obtained during the CAA, was suggested by Spyrou.\(^{18,27,28}\)

For large $n$, $(1 - e^{-n\lambda T})$ tends to unity, Equation (5) can be reduced as

$$D_c = D_1 \left( 1 - \frac{e^{-\lambda T}}{1 - e^{-\lambda T}} \right)$$

$$= \frac{nD_1}{(1 - e^{-\lambda T})} - \frac{D_1 e^{-\lambda T}}{(1 - e^{-\lambda T})^2}$$

(10)

where $D_c$ is a linear function of $n$ with all other parameters constant. Plotting $D_c$ as a function of $n$, the slope of the line is given by Equation (11):

$$a = \frac{D_1}{(1 - e^{-\lambda T})}$$

(11)

and the intercept by Equation (12):

$$b = \frac{D_1 e^{-\lambda T}}{(1 - e^{-\lambda T})^2}$$

(12)

The half-life of the nuclide measured can be calculated by Equation (13):

$$t_{1/2} = \frac{T \ln 2}{\ln (1 - a/b)}$$

(13)

For this purpose, it is necessary to store the spectra of each individual cycle instead of using the accumulative spectrum.

2.4 Dead Time and Pileup Correction

CAA is usually employed for the determination of short-lived nuclides in a matrix of long-lived activation products. The activity of a sample not only changes considerably during a counting period owing to short-lived nuclide decay but also increases from cycle to cycle because of the matrix activity owing to the accumulation of longer-lived products. Consequently, a rapidly changing dead time is encountered in a counting period. The basic Equation (14) for dead time correction was given by Schonfeld\(^{29}\):

$$C = \int_0^{t_i} A_0 e^{-\lambda t} \left[ 1 - DT(t) \right] \, dt$$

(14)

where $C$ is the actual acquired net counts in photopeak of interest, $A_0$ is the true initial photopeak count rate, and $DT(t)$ is the fractional analyzer dead time at time $t$. In order to implement this correction, the variation of fractional dead time during the counting period must be known. By the least square fitting of the experimental data, Egan et al.\(^{30}\) found that $DT(t)$ is an exponential function of $t$, and it can be expressed by Equation (15):

$$DT(t) = B + Ce^{-kt}$$

(15)

where $B$, $C$, and $k$ are constants. Hence, a correction factor ($f$) for dead time in a counting period can be obtained using Equation (16).

$$f = \frac{\int_0^{t_i} A_0 e^{-\lambda t} \, dt}{\int_0^{t_i} A_0 e^{-\lambda t} (1 - B - Ce^{-kt}) \, dt}$$

(16)

For cyclic activation with $n$ cycles, the correction factor ($F_n$) can be expressed by Equation (17):

$$F_n = \frac{\sum_{n=1}^{n} \int_0^{t_i} A_0 e^{-\lambda t} \, dt}{\sum_{n=1}^{n} \int_0^{t_i} A_0 e^{-\lambda t} (1 - B - Ce^{-kt}) \, dt}$$

(17)

$DT(t)$ not only varies with $t$ in a counting period but also differs from one cycle to another. $F_n$ is also a function of $n$.

It was observed that the correction factor for the dead time, $f$, is approximately equal to the ratio of clock time
to live time obtained from the multichannel analyzer clock data in each counting period.\textsuperscript{(30)} Hence, it is usually used to correct for dead time after each cycle. In this case, it is important to store the $\gamma$-spectra of each cycle period and correct the counts of interest nuclide for dead time before summation of individual spectrum.

With increasing analyzer dead time, the pulse pileup loss (also called summing effects or coincidence losses) will become more serious. It can be overcome satisfactorily by introducing a pulser with constant frequency into the system.\textsuperscript{(30)} The ratio of the areas under the pulser peaks, after dead time correction, was measured and the pileup correction factor was defined as $F_p$ (Equation 18):

$$F_p = \frac{\text{Pulser peak area (at } \sim 0\% \text{ dead time)}}{\text{Pulser peak area (at sample dead time)}}$$  \hspace{1cm} (18)

However, pileup correction, unlike dead time, is implemented on the cumulative spectrum.

Wytenbach\textsuperscript{(31)} suggested another way to correct the pileup loss by using the real time (cock time), $t_c$, and the live time of the measurement, $T_c$ (Equation 19):

$$F_p = \frac{P}{P_0} = 1 - \frac{2\tau}{\nu} \left( \frac{t_c}{T_c} - 1 \right)$$  \hspace{1cm} (19)

where $P_0$ is the true photopeak count rate without coincidence losses, $P$ is the actual photopeak count rate including pileup, $\nu$ is a constant of the detector system, and $\tau/\nu$ can be measured by plotting $P/P_0$ versus $t_c/T_c$ and subsequently be used to correct other spectra. However, it should be considered that actually $\tau$ depends on the energy of the $\gamma$ ray measured.\textsuperscript{(32)} In addition, the use of a loss-free counting system with pileup rejection will avoid this problem.\textsuperscript{(33)}

### 2.5 Cumulative Activation Analysis

Guinn\textsuperscript{(34)} suggested another method similar to CAA, which is based on the irradiation and counting of a number of replicates of the same sample and the individual spectra are summed to give one total spectrum. As the activity derived from activated matrix elements is the same for each cycle, the background count and the dead time in each cycle does not increase with the increasing number of replicates. Hence, this will lead to a better precision and detection limit than that of normal CAA for short-lived nuclides. The main advantage of this method is that a large representative sample can be measured even in the case of material, which activates to form high radioactive products.

By this method, Parry\textsuperscript{(35,36)} measured rhodium, silver, and gold in some geological samples and reference materials and found that the detection limit was improved by a factor of 4.4–4.7 using 20 replicates in accordance with the theoretical factor of $n^{1/2}$. The main disadvantage of this method is the long time required for the preparation of $n$ samples for each material to be analyzed, and the application is limited by the amount of samples available.

For overcoming the relatively high error resulted from inhomogeneity of sample, Farooqi et al.\textsuperscript{(37)} suggested combining this technique (called mass fraction) with normal CAA to analyze fluorine in diet sample. In addition to good precision, a lower detection was also obtained.

### 3 CLASSIFICATION AND FACILITIES OF CYCLIC ACTIVATION ANALYSIS

According to source-target-detector system, Spyrou\textsuperscript{(18)} classified CAA in the following five types:

1. An “external” beam of incident radiation, which can be mechanically chopped or electronically pulsed with stationary target, such as pulsed neutron source (or called neutron generator) as used by Givens et al.\textsuperscript{(4,5)} in which the waiting time can be as short as 0.5 ms. This type of CAA was termed real CAA. However, the radiation flux supplied in this system is usually low, i.e. the total $4\pi$ neutron flux is only $1.16 \times 10^{11}$ $n$ $s^{-1}$ in the facility used by Givens et al.\textsuperscript{(4,5)}

2. An “external” beam providing a continuous source of incident radiation, with the target moving into and out of the beam either linearly or by rotation. The typical source of this type of CAA is neutron source produced by an accelerator with which, in addition to fast neutron, thermal neutrons can be supplied. Further, the energy of neutron can also be chosen, which is very useful to avoid some interfering nuclear reactions. The neutron flux supplied usually ranges from $10^6$ to $5 \times 10^{11}$ $n$ $cm^{-2}$ $s^{-1}$. Most fast neutron CAA has been carried out in this kind of facility.\textsuperscript{(1,2,14,38,39)}

3. An “enclosed” beam where the target is made to oscillate either cyclically or linearly into and out of the beam. The main radiation source in this type of CAA is the core of reactor. Not only can a high neutron flux ($10^{11} - 10^{12}$ $n$ $cm^{-2}$ $s^{-1}$) be used but also the thermal, epithermal, and fast neutron activation can be carried out. By detection of $\gamma$ ray by coaxial HpGe (or Ge(Li)) and low-energy photon detector and delay neutron by neutron detector, most elements can be determined with a high accuracy and a good detection limit. Most CAA work has been implemented using this type of system.\textsuperscript{(7–13,18–20,23,25,27,30,37)} Figure 8 shows a schematic diagram of this system. Similar facilities
have been set up for CNAA in such institution as University of London Reactor Center, UK,\(^{(10)}\) Dalhousie University, Canada,\(^{(9)}\) MNSR, China Institute of Atomic Energy,\(^{(13)}\) MNSR, Syria,\(^{(40)}\) MNSR, Shenzhen University, China (Personal communication), JRRS-SM, Japan Atomic Energy Research Institute, Japan,\(^{(41)}\) Atominstitut, Vienna,\(^{(12)}\) University of Missouri, USA.\(^{(39)}\)  

4. The case of an isotopic source, where the target remains stationary but the source is made to oscillate to and from the target position. The most commonly used isotope neutron source is Am–Be and 252Cf neutron source.\(^{(42,43)}\) A useful application of this system is in vivo NAA. The neutron flux supplied in this system is only \(10^4 – 10^6\) n cm\(^{-2}\) s\(^{-1}\), and the detection limit is therefore high.  

5. A primary source creating a secondary source, which in turn provides the irradiation beam for the target. An example of this case is the neutron interrogation system described by Mardani,\(^{(44)}\) where a neutron beam is made to impinge on nuclear fuel, which on fission produces neutrons that act as the secondary source for the activation of a continuously circulating fluid (freon) containing fluorine. The reaction \(^{19}\)F(n, \(\alpha\))\(^{16}\)N was used to determine the amount of fissile material in the fuel element by cyclic measurement of \(^{16}\)N (7.2 s).

In all types of CAA, most work has been carried out using CNAA. Depending on the neutron source used, CNAA can be classified as reactor, neutrons produced by accelerator and neutron generator, and isotopic source CNAA. On the basis of the energy of neutron, it can be classified as thermal, epithermal, and fast neutron CAA; on the basis of the radiation emitted from the activated nuclide, it can be classified as \(\gamma\) ray and delay neutron CAA. Table 1 lists the elements that can be determined using different types of CNAA. The nuclear parameters of elements probably detected by cyclic thermal NAA and cyclic fast neutron activation analysis (FNAA) using their short-lived nuclides (\(T_{1/2} < 100\) s) are listed in Tables 2 and 3, respectively. In addition to the elements listed in Tables 2 and 3, some elements with nuclides of medium half-lives (\(T_{1/2} > 100\) s), such as Al, Mg, Ca, V, Cu, S, Mn, Na, Cl, K, Ti, Co, Br, I, In, Sr, U, and Th, may occur in the cumulative \(\gamma\)-spectrum or can be further counted a few minutes after the last cycle. These can, therefore, also be determined simultaneously.

4 APPLICATION OF CYCLIC ACTIVATION ANALYSIS

CAA was first suggested for the analysis of geological materials,\(^{(3–5)}\) but with its development and maturity, this technique has been used in every field of elemental analysis, and there are numerous articles dealing with the application of CAA. Some main applications are discussed below.

4.1 Determination of Se, F, and O in Biological Materials

Selenium is known as a biological essential trace element, its concentration in normal biological tissues is lower than \(1.0 \mu g\) g\(^{-1}\), and a sensitive analytical technique is...
required for its quantitative determination. NAA is a sensitive method for the determination of Se. In most cases, analysis is performed by measuring $^{75}$Se, which has a longer half-life (120 days), and therefore needs a relatively long analytical period (weeks to months). The uses of short-lived isotope $^{77m}$Se can considerably reduce the analytical time to a few minutes and thus the analytical expense. However, the detection limit and analytical precision are usually not good enough by conventional single-shot irradiation due to quick decay of $^{77m}$Se. CNAA satisfactorily solved this problem, and therefore has been widely used for this purpose.\(^{(13,19,20,30)}\) Figure 9 shows $\gamma$-spectra of $^{77m}$Se in biological sample acquired by conventional single-shot NAA and CNAA. Although the background is increased, the signal of $^{77m}$Se and the signal-to-background ratio are significantly improved by CNAA. Shi et al.\(^{(48)}\) compared the conventional NAA with CNAA for the determination of Se in different food samples. In general, the detection limit of Se by measuring $^{77m}$Se ($t_i : t_d : t_c = 30 s : 10 s : 30 s$) is better than that by measuring $^{75}$Se ($t_i : t_d : t_c = 17 h : 16 days : 12 h$) using the same neutron flux by a factor of 1.5, and the detection limit using CNAA with three cycles is two times better than the single-shot NAA.

Figure 9 shows the detection limit and analytical precision for Se in human hair by conventional and cyclic NAA, respectively. It can be clearly seen that both detection limit and analytical precision were significantly improved by CNAA. Considering the interference from $^{38m}$Cl ($t_{1/2} = 0.715 s$), the optimal time parameters of CNAA of biological samples for Se given by Egan et al.\(^{(30)}\) are $t_i = 19.5 s, t_d = 3 s, t_c = 18 s, t_w = 1 s$. Under these conditions, the samples with Se concentrations as low as 10 ng g$^{-1}$ have been analyzed,\(^{(49)}\) and usually 10 samples can be treated in 1 h. CNAA has also been used for the determination of Se in urine\(^{(50)}\) and nail,\(^{(51)}\) and as low as 1.8 ng g$^{-1}$ Se in urine samples has been measured.\(^{(50)}\) In MNSR, China Institute of Atomic Energy, more than 2000 varieties of biological samples, such as human and animal tissues and body fluids, diet, and vegetation, have been analyzed for Se using this method in the last few years.

Fluorine is another human essential trace element and a bone seeker. Dental caries and osteoporosis were thought to be related to the intake of F and

The concentration in the tissues. Only one isotope, $^{20}$F, can be used for its determination by NAA. Owing to very short half-life of $^{20}$F (11.2 s), CNAA was therefore widely used for its determination.\(^{(9,11,37,52)}\) Under the conditions of $t_i = t_c = 10$ s and $t_d = t_w = 2$ s, a detection limit of 1–10 $\mu$g g$^{-1}$ for diet sample can be obtained by 14 cycles.\(^{(37)}\) For the same condition, the detection limit of F in bone was reported to be 52 $\mu$g g$^{-1}$;\(^{(52)}\) this is mainly attributed to the high background under $^{20}$F $\gamma$-ray peak (1633 keV), which is due to high $^{28}$Al signal (1779 keV) in the spectra for bone samples. Since the reactions $^{23}$Na(n, $^{4}$He) and $^{20}$Ne(n, p)$^{20}$F can also produce $^{20}$F, and the concentration of Na is much high in biological samples, the sodium interference must be corrected for. In addition, this interference can be significantly reduced using well-thermalized neutrons, such as irradiating in a thermal neutron irradiation facility in research reactors.

4.2 Determination of Pb, F, Sc, and Ag in Environmental Samples

Lead is well known as a toxic element and its distribution as a pollutant is widespread. It is, therefore, of interest to determine its concentration in a variety of environmental materials. Lead cannot be determined by thermal NAA unless a very short-lived radionuclide $^{207m}$Pb was used.\(^{(54)}\) However, the half-life of $^{207m}$Pb of only 0.8 s makes it difficult to be measured using conventional NAA method. By using a fast transfer pneumatic system, Egan and Spyrou\(^{(22)}\) determined lead in some environmental samples. Under the conditions, $t_i = t_c = 2$ s, $t_d = t_w = 1$ s, and 50 cycles, the sensitivity in an interference-free matrix

</table>

was found to be $5 \mu g$, and a detection limit of $30 \mu g^{-1}$ was reported for biological matrix.

Owing to a high-resonance integral cross section of reaction $^{19}$F(n, $\gamma$)$^{20}$F, Parry et al.$^{(55)}$ determined fluorine in moss and soil sample with an improved detection limit by using epithermal neutron and cyclic activation.

Silver and scandium are usually determined by using their long-lived nuclides, $^{110}$Ag and $^{46}$Sc. However, the use of CNA not only reduces the analytical time but also improves the detection limit of these two elements by using their short-lived nuclides, $^{110}$Ag and $^{46m}$Sc. Chatt et al.$^{(9,20)}$ and Spyrou et al.$^{(23)}$ have used CNA to analyze some environmental samples for Sc and Ag as well as other elements, such as Dy, Hf, Se, Al, V, etc.

In addition, fast neutron CAA was also used for the determination of Pb and F in environmental samples by using reactions $^{208}$Pb(n, 2n)$^{207}$Pb and $^{19}$F(n, p)$^{19}$O; a comparable detection was reported for the determination of F by epithermal neutron CAA and fast neutron CAA.$^{(55)}$ In addition to Pb and F, fast neutron CAA has also been used for many other elements such as As, Ce, Nd, and Hf.$^{(59)}$

4.3 Determination of O, Sc, Si, Al, Ag, Au, Rh, Hf, Pb, and U in Geological and Industrial Materials

CAA was proposed early by Caldwell et al.$^{(3)}$ for the elemental analysis of lunar and planetary samples. Using this technique,$^{(4,5)}$ they successfully detected O, Si, Mg, and Al by fast neutron reactions, $^{16}$O(n, p)$^{16}$N, $^{28}$Si(n, p)$^{28}$Al, $^{24}$Mg(n, p)$^{24m}$Na, and $^{27}$Al(n, $\alpha$)$^{24}$mNa. Joshi and Agrawal$^{(16)}$ determined Pb and Na in soil samples by using fast neutron reactions $^{208}$Pb(n, 2n)$^{207}$Pb and $^{23}$Na(n, $\alpha$)$^{20}$F under the condition of $t_i = t_c = 2.5s$, $t_d = t_w = 0.4s$ and 14 cycles. Their results indicated that besides Pb and Na, other eight elements, such as O, Si, Mg, As, Ce, Hf, Nd, and In, could also be determined by this method. Chatt et al.$^{(9)}$ determined Hf in Zirconium wire and Pb in brass by thermal neutron CAA, the detection limits reported are 0.93 $\mu g^{-1}$ and 3.6%, respectively. Parry$^{(35,36)}$ analyzed some geological materials for Rh.
Ag by thermal neutron CAA and Au by fast neutron CAA; she also analyzed F in industrial samples by used fast neutron CAA. Owrang et al. reported a fast neutron CAA method for the in situ determination of oxygen in oil by using a neutron generator, a few milligrams of oxygen in oil sample has been determined, using this technique, the concentration of oxygen in metal oxides could also be measured.

Uranium is usually determined by measuring $^{239}$Np produced by $^{238}$U(n, $\gamma$)$^{239}$U($\beta^-$)$^{239}$Np reaction. However, by measuring delay neutron after thermal neutron irradiation and cyclic activation, the detection limit can be significantly improved. In addition to geological sample, it can also analyze super-pure material, such as single-crystal silicon for uranium in nanogram per gram level. Song used this technique to analyze a variety of geological and industrial samples for uranium; a detection limit of 0.1 ng g$^{-1}$ was reported.

5 CONCLUSION AND PERSPECTIVE

Since it was first proposed in the beginning of 1960s and rapidly developed in 1970s and 1980s, CAA has become a useful and mature technique for elemental analysis. Although some new CAA facilities were installed, in recent years, only some limited improvement on methodology was made. However, with the increase in CAA facilities, this technique is being applied in more wide fields, and with the increasing interest in using short-lived nuclides for activation analysis, CAA is attracting more attention. However, CAA, as one of the activation analytical techniques, can only be a supplement and not instead of the conventional activation analysis.

Comparing with conventional activation analytical techniques, CAA offers several advantages: (i) significant improvement of detection limit, analytical precision and accuracy for elements determined by using short-lived nuclides; (ii) short experimental time, hence reduced analytical expense and increased analytical capacity; (iii) capability of determining the degree of homogeneity of a sample by analyzing several portions of it for single cycles (cumulative activation); (iv) simultaneous determination of short- and medium-lived nuclides; and (v) estimating or confirmation of half-life of short-lived nuclides. However, CAA also has some disadvantages, e.g. (i) limited number of elements analyzed, i.e. only <50% of elements analyzed by conventional NAA can be determined by CNA; (ii) some special equipment or changes of normal equipment used in conventional activation analysis are needed; (iii) dead time and pileup correction must be made; (iv) interference from impurity elements in shuttle rabbit material cannot be avoided and a special compressed gas (such as N$_2$, not air) should be used to transfer sample for reduced interference from $^{41}$Ar and other nuclides in activated air.

In comparing with nonnuclear analytical techniques, such as ICP–MS, owing to rapidity, nondestructive analysis, and in situ analysis, CAA as one of the activation analysis techniques is more competitive. However, with the improvement of ICP–MS technique (especially nondestructive analysis by laser ablation inductively coupled plasma mass spectrometry (LA–ICP–MS)) and its popularity, the application of CAA (including all activation analysis techniques) is becoming less.

ABBREVIATIONS AND ACRONYMS

- $\sigma$: Activation cross section
- $C$: Actual acquired net counts in photopeak of interest
- $f$: Correction factor for dead time in one cycle
- $F_n$: Correction factor for dead time of $n$ cycles
- $F_p$: Correction factor for pileup
- $t_c$: Counting time
- $S/m$: Counts per unit mass element of interest
- $T$: Cycle period ($T = t_1 + t_d + t_c + t_w$)
- CAA: Cyclic activation analysis
- CNAA: Cyclic neutron activation analysis
- $\lambda$: Decay constant ($\lambda = \ln 2/t_{1/2}$)
- $t_d$: Delay time (the time interval between the end of irradiation and the start of counting)
- $D_1$: Detector response (or the number of counts)
- $D_n$: Detector response in $n$th cycle
- $\varepsilon$: Efficiency of the detector
- FNAA: Fast neutron activation analysis
- DT(t): Fractional analyzer dead time at time $t$
- $t_{1/2}$: Half-life of the nuclide of interest
- ICP–MS: Inductively coupled plasma mass spectrometry
- LA–ICP–MS: Laser ablation inductively coupled plasma mass spectrometry
- NAA: Neutron activation analysis
- $n$: Number of cycles
- $N$: Number of target nuclei
- $N^*$: Number of radioactive nuclei
- PCAA: Pseudocyclic activation analysis
- $L_d$: Qualitative detection limit
CYCLIC ACTIVATION ANALYSIS

Φ

Radiation (neutron) flux intensity

δ

Relative standard deviation

I₀

Resonance integral cross section

σ₀

Thermal neutron activation cross section

P

The actual photopeak count rates including pileup

P₀

The true photopeak count rates without coincidence losses

Tₖ

The live time of the measurement

bDₖ

The cumulative detector response for the nuclide making the major background contribution to the signal from the nuclide of interest

τᵢ

Time of irradiation

Dₖ (ₙDₖ)

Total cumulative detector response in all n cycles

Tₜ

Total experiment time

A₀

True initial photopeak count rate

tₘ

Waiting time (the time interval between the end of counting and the start of irradiation)

Direct Reading Instruments for the Determination of Aerosols and Particulates

David Y.H. Pui and Da-Ren Chen
University of Minnesota, Minneapolis, USA

1 Introduction

1.1 Aerosols and Particles

Solid and liquid particles suspended in a gas are referred to as aerosols. The suspending medium can be air, or some other gases, such as argon, nitrogen, helium, etc. Aerosols have found numerous scientific and technical applications. Beneficial applications include pharmaceutical aerosols for medical inhalation therapy or diagnosis, industrial aerosols for coating wave guides, refractories, gas sensors and semiconductors, as well as particles of modern materials for forming advanced ceramics, optical and optoelectronic devices, cosmetic products, paint pigments, and catalysts. Harmful effects of aerosols include atmospheric aerosols that contribute to urban air pollution and global radiation balance, dust particles ingested by engines causing premature failure of the equipment, and particles deposited on semiconductor wafers causing device failure and product yield loss.

Aerosols and particles can be analyzed by collecting them on a filter or a sampling surface for subsequent microscopic, gravimetric, or chemical analyses. The collection by the samplers gives an integrated sample and a time averaged concentration over a period of hours or days. Direct reading instruments carry out the sampling and analysis within the instrument and the property of interest can be obtained in near real-time. Direct reading instruments are available to cover particles in the size range of 0.002 to 100 µm. These instruments have fast time response and can follow rapid changes in both particle size and concentration. Good counting statistics can also be obtained because repeated measurements can be performed in a short time. However, these instruments usually rely on indirect sensing techniques and more calibration efforts are usually required.

1 INTRODUCTION

1.1 Aerosols and Particles

Solid and liquid particles suspended in a gas are referred to as aerosols. The suspending medium can be air, or some other gas, such as argon, nitrogen, helium, etc. The branch of science dealing with such gas-borne particles is known as aerosol science.

Aerosol is one of three types of dispersed systems found in nature and in various technical applications: aerosol (solid or liquid particles dispersed in a gas), hydrosol (solid or liquid particles suspended in a liquid), and foam (small gas bubbles dispersed in a solid or liquid).

Aerosols have found numerous scientific and technical applications. Atmospheric aerosols due to air pollution, e.g. smog, are the principal cause of visibility degradation. They contribute to the cloud formation process and affect global radiation balance. Airborne lead, asbestos, and other harmful substances can lead to serious health consequences when inhaled. Atmospheric dust particles ingested by an engine, a gas turbine, or other power generating equipment can cause wear and the premature failure of the equipment. Particles depositing on semiconductor wafers during manufacturing of large-scale integrated circuit chips can cause defects, leading to device failure and loss of product yield.
Aerosols are used in many beneficial applications such as the production of advanced materials and the use of aerosols for medical inhalation therapy or diagnosis. Aerosols are used in material synthesis to produce powders and bulk materials, and for coating optical and microwave waveguides. Owing to their simplicity and freedom from contamination, aerosol processes are used in the production of a variety of modern materials, such as advanced ceramics, carbon black, paint pigments, and high-temperature superconductors, and for coating waveguides, refractories, gas sensors, and semiconductors. An exciting new area for the materials industry is the production of nanostructure materials consisting of nanometer-size particles. Nanoparticles possess many desirable properties, including improved hardness, reduced internal friction (i.e. improved ductility), reduced melting point, and special optical and magnetic properties. These properties are the basis of many so-called “high-tech” applications, including quantum dots, drill bit coatings, fuel cells, and tunable lasers.

Biotechnology is an emerging area for aerosol applications. Determination of the molecular weights of biopolymers, including oligonucleotides and proteins, is of fundamental importance to biotechnology development. These biomolecules with molecular weights up to 130,000 are, in essence, nanometer particles. Aerosol technique is used as a supplement to mass spectrometry for detecting and measuring these macromolecule particles.

### 1.2 Direct-reading Instruments

Particle concentration, size distribution and chemical composition are used to characterize an aerosol system. The concentration can be weighted by number (particles cm\(^{-3}\)), surface (\(\mu\text{m}^2\text{cm}^{-3}\)), volume (\(\mu\text{m}^3\text{cm}^{-3}\)), or mass (\(\mu\text{g}\text{cm}^{-3}\)) in a unit volume of gas medium. Other physical parameters, such as the total light scattering coefficient of the aerosol plume, may also be important and need to be measured.

Aerosols can be characterized by using sampling devices or by direct reading instruments. In the sampling devices, aerosols are collected on a substrate for subsequent gravimetric and/or chemical analysis, e.g. wet-chemical technique or proton induced X-ray fluorescence technique. The collection is usually done with a filter sampler to give an integrated sample and a time averaged concentration measurement. Attention must be given to the possibility of chemical interactions among the collected particles and of artifact formation due to reaction between the substrate and the more reactive chemical species in the gas phase, e.g. the reaction of glass fiber filters with \(\text{SO}_2\) in air.

Direct-reading instruments involve sampling and analyzing aerosols within the instruments, and properties of interest can often be obtained in real-time. Direct-reading instruments are available to cover particles in the size range of 0.002 to 100 \(\mu\text{m}\). These instruments have fast response and can follow rapid changes in both particle size and concentration. Recent advances enable near real-time measurements of particle chemical compositions. Good counting statistics can also be obtained because repeated measurements can be performed in a short time. However, these instruments usually rely on indirect sensing techniques and more calibration efforts are usually required.

### 2 PARTICLE SIZE DISTRIBUTIONS AND INSTRUMENT MEASURING RANGES

Aerosol particles may consist of microscopic bits of materials in the form of molecular clusters of only a few nanometers in diameter, to particles of a near macroscopic size of a fraction of a millimeter in diameter. The nominal size range of interest in aerosol science is 0.002 to 100 \(\mu\text{m}\). The lower size limit, 2 \(\text{nm}\), corresponds to the smallest particles that can be detected by a direct reading instrument, e.g. the ultrafine condensation particle counter (UCPC). The largest particles are those that would begin to fall out from a gas medium too quickly, e.g. rain drops, to be considered an aerosol. Particle size determination is important because many aerosol properties are a function of particle size. Particle deposition on wafers in semiconductor manufacturing and deposition in different regions of the human respiratory tract in health studies are determined by particle size.

Particle size distribution is usually presented as particle concentration in number, surface or volume (mass) weightings as a function of particle size. Vast databases have been collected on atmospheric size distributions from many air pollution studies. As a result, there is now a general understanding of the aerosol formation and removal mechanisms in the atmosphere. Figure 1 shows a volume-concentration size distribution of atmospheric aerosols measured near a combustion source, i.e. automobile traffic. Atmospheric aerosol is seen to consist of three modes and cover a size range of 0.002–100 \(\mu\text{m}\). The three principal modes are referred to as the nuclei mode (0.002–0.05 \(\mu\text{m}\)), the accumulation mode (0.05–2 \(\mu\text{m}\)) and the coarse particle mode (2–50 \(\mu\text{m}\)). The accumulation mode and the coarse particle mode can be observed in nearly every atmospheric measurement, whereas the nuclei mode can only be measured near an aerosol source involving high temperature and other gas-to-particle conversion processes, e.g. combustion and photochemical...
The measured particle size will be different for different as its gravimetric, optical, aerodynamic, mechanical, or from one of many possible particle properties, such data in particle “size”, this “size” is actually derived aerosol properties. Although many instruments provide size in the atmosphere.

principles are needed to cover the five decades of particle size, several instruments based on different operating dynamic range of approximately two decades in particle they cover. Since most measuring instruments have available particle size analyzers and the size ranges size range from 0.002 to 100

carbon, ammonium, lead and other trace constituents. Particles in the nuclei and accumulation modes contain sulfates, nitrates, elemental and organic carbon, ammonium, lead and other trace constituents. This evidence suggests that the formation mechanisms are different for the fine and coarse particle modes. It is expected that the removal mechanisms will also be different owing to the wide particle size range covered by the three modes. A comprehensive review of the formation and removal mechanisms of atmospheric aerosols can be found in the paper by Whitby.

A variety of instruments are available to measure particle size distribution and concentration in the entire size range from 0.002 to 100µm. Figure 2 shows the available particle size analyzers and the size ranges they cover. Since most measuring instruments have a dynamic range of approximately two decades in particle size, several instruments based on different operating principles are needed to cover the five decades of particle size in the atmosphere.

Different direct-reading instruments measure different aerosol properties. Although many instruments provide data in particle “size”, this “size” is actually derived from one of many possible particle properties, such as its gravimetric, optical, aerodynamic, mechanical, or force field mobility behaviors. It is expected that the measured particle size will be different for different instruments used. The diameter of an equivalent sphere is usually defined to specify the particle size measured by instruments based on different principles. For example, the aerodynamic equivalent sphere or Stokes equivalent sphere may be used to designate the same particle, and refer to the diameter of a unit density sphere or the same density sphere, respectively, having the same settling speed as the particle in question. Other equivalent sphere diameters can be based on other particle properties, e.g. diffusion, electrical mobility, and light scattering. Thus, the particle sizes measured by different principles may not be directly compared without some correction of the data to account for the differences.

3 SIZE DISTRIBUTION MEASUREMENT

Figure 2 shows the available commercial direct reading instruments for size distribution measurements. They cover the entire size range of interest from 2 nm to 100µm. The measured size distributions can be integrated to obtain the total number, surface, and volume (mass) concentrations. Alternatively, these total concentrations can be measured by compact, relatively inexpensive integral concentration detectors (Figure 2). These detectors also cover most of the five decades in particle size range. The upper limits are often set by the efficiency of the sampling inlets. Since most direct reading instruments rely on particle detection by electronic transducers, monodisperse aerosol standards are needed to calibrate these instruments. Some of the principal methods for generating these aerosol standards in the five decades of particle size range are also shown in Figure 2.
3.1 Differential Mobility Analyzer

The high electric mobility of submicrometer particles in an electric field makes it possible to separate and classify electrically charged aerosol particles. If the electric mobility is a monotonic function of the particle size, size classification or size distribution, measurement can be made on the basis of the particle electrical mobility.

Figure 3 shows the principle of the differential mobility analysis technique. Charged aerosol and clean sheath air are introduced into the annular space between two concentric cylinders. Clean air flows along the inner cylinder that consists of a narrow slit on the downstream side of the cylinder. A high voltage is applied to the inner cylinder relative to the outer cylinder that is electrically grounded. The electric field between the two cylindrical electrodes causes charged particles to be attracted to the inner cylinder. Small particles with higher electrical mobility will be collected above the slit, while the large particles with lower electrical mobility will be collected below the slit or be carried away by the main flow. Only those particles with the correct electric mobility and of narrow mobility range (monodisperse) will be extracted by the slit flow and detected by a particle counter downstream. By varying the voltage on the inner cylinder and measuring the corresponding particle concentration, a mobility distribution can be obtained which can be inverted to obtain the particle size distribution.

Knutson and Whitby obtained an analytical equation to describe particle motion inside the differential mobility analyzer (DMA). They showed that the resolution of the instrument is a function of aerosol/sheath flow ratio in the DMA. High resolution can be obtained by reducing the flow ratio. Recent numerical studies by Chen and Pui and Chen et al. have demonstrated that the DMA
is capable of resolving particle size distribution with a geometrical standard deviation of 1.01. The numerical codes also facilitated the design of a new generation of DMAs such as the nanometer aerosol differential mobility analyzer (Nano-DMA) used for measuring particle size distribution down to 3 nm.\textsuperscript{9}

Figure 4 shows a schematic diagram of the available commercial DMAs in three different configurations, namely the TSI-DMA,\textsuperscript{10} the Hauke 3/150\textsuperscript{11} and the Spectromete de Mobilité Electrique Circulaire (SMEC).\textsuperscript{12} Another radial-design DMA similar to that of SMEC was developed by Zhang et al.\textsuperscript{13} Fissan et al.\textsuperscript{14} evaluated the three different types of DMAs and found good performance for particle size larger than 10 nm. Below 10 nm, the instrument resolution and sensitivity (particle loss within the DMA) were degraded due to the high diffusivity of the nanoparticles. Subsequent development by Chen et al.\textsuperscript{9} has resulted in a new Nano-DMA that is optimized for the nanoparticle size range. The Nano-DMA, shown schematically in Figure 5, provides a three-fold increase in the resolution and a three-fold decrease in the diffusional loss than the best available DMA.

One significant advance on using the DMA for particle size distribution measurement was developed by Wang and Flagan.\textsuperscript{15} They made use of a scanning electric field, in place of changing the electric field in discrete steps in the traditional differential mobility particle sizer (DMPS) technique, to speed up the cycle time of the mobility analyzer considerably (from a cycle time of 3 min to less than 10 s). Using an exponential ramp in the field strength, the particles are classified in the time-varying electric field while maintaining a one-to-one correspondence between the time a particle enters the classifier and the time it leaves. The scanning mobility particle sizer (SMPS) is a commercial instrument that makes use of this scanning feature.

The DMA technique requires that the classified particles be electrically charged to a known level. Particles can acquire charges by exposing them to high concentration of either unipolar ions or bipolar ions. Devices are available based on a unipolar charging technique\textsuperscript{10} or a bipolar charging technique.\textsuperscript{16} Recent advances include the development of a high efficiency, high throughput unipolar aerosol charger for nanoparticles by Chen and Pui.\textsuperscript{17}

### 3.2 Diffusion Batteries

Since the rate of diffusion of aerosol particles to a solid surface is a function of particle size, particle loss in a diffusion collector can be used for size distribution measurement. The technique has been used for many years for size distribution measurements of small particles below 0.1 µm.\textsuperscript{18} A simple diffusion battery design consists of a single capillary tube, or a capillary tube bundle through which the aerosol is passed. A condensation particle counter (CPC) is then used to measure the upstream and downstream aerosol concentrations. The aerosol penetration through the diffusion collector can then be taken as a measure of particle size. By arranging a number of these diffusion collectors in series, the size distribution of the aerosol can be measured.

Several novel diffusion batteries have been developed by Sinclair,\textsuperscript{19} who used metal disks containing uniform parallel holes of a finite length – the so-called collimated hole structure – and layers of fine stainless steel screens as diffusion collectors. Detailed studies of wire screens
as diffusion collectors have been reported. Various sophisticated data reduction techniques based on Simplex and other minimization techniques for the diffusion battery have also been reported. The diffusion battery measurement is now widely accepted.

The diffusion battery has also been used as a particle separator for size selective particle sampling. Lundgren and Rangaraj use it for in-stack particle sampling. George and Sinclair et al. made use of the screen diffusion batteries to measure the submicron radioactive aerosols. One of the requirements for accurate diffusion battery measurement is that the counting efficiency of the CPC should be well characterized.

### 3.3 Optical Particle Counter

The optical particle counter (OPC) is widely used for size distribution measurements in both indoor and outdoor...
environments. Figure 6 shows the operating principle of the OPC. Single, individual particles are carried by an air stream through an illuminated viewing volume in the instrument and cause light to be scattered to a photodetector. The photodetector generates a voltage pulse in response to each particle passing through the viewing volume. The pulse amplitude is then taken as a measure of particle size. The pulse is then counted and processed electronically to yield a pulse-height histogram, which is then converted to a histogram for particle size distribution using an appropriate calibration curve. Many commercial counters using an incandescent light source have been developed for particle size distribution measurement in the range 0.3 µm to approximately 10 µm. Recent advances include the use of laser illumination to achieve lower detection limits down to 0.05 µm.

OPCs differ widely in their design and performance characteristics. Table 1 gives a selected list of OPCs available commercially. The PMS counter uses the “active scattering” principle, in which the particles are passed...

a  mm, multimode; LD, laser diode; L, laser; Xe, xenon.

through the resonant cavity of a helium–neon laser. The Hiac/Royco instrument uses a helium–neon laser and an external scattering volume. In contrast, the TSI instrument uses a solid-state laser diode to obtain a small, light-weight portable sensor. They can be differentiated by the light source (laser, laser diode, or white light) they use, the sampling flow rate of the instrument, the number of channels of data the instrument provides, and other distinguishing characteristics, such as portability and ability to be interfaced with computers.

In general, an instrument using a laser source, particularly of the “active scattering” type, can detect smaller particles than a corresponding instrument using an incandescent light source because of the higher
illuminating intensity of the laser. The lower detection limit of the white-light and laser diode counters is usually around 0.3 µm, whereas “active scattering” laser counters can detect particles as small as 0.1 µm and below. A higher flow rate instrument can count more particles in a given time period than an instrument of a lower sampling flow rate. However, the particle coincidence level of high flow rate instruments is usually much lower. OPCs of this type are particularly important for particle counting in a low concentration environment, such as in cleanrooms. A lower flow rate instrument has higher resolution and can detect smaller particles than the high flow counter. A sampling flow rate of 1 cubic foot per minute (cfm) is usually considered high and a flow rate of 0.01 cfm is usually considered low.

The OPC response, which gives a functional relationship between the pulse height and the particle size, depends on both the instrument properties and the particle properties. The former includes optical design, illumination source, and electronics gain, and the latter includes particle size and shape, refractive index, and orientation of nonspherical particles with the incident beam. The relative response of the OPC as a function of particle size can be calculated by means of the theory of electromagnetic scattering developed by Mie. The calculation for some white light counters has been reported by Cook and Kerker. More recent studies have concentrated on laser particle counters.

To determine the absolute voltage-size response of the OPCs, as well as other instrument characteristics, such as resolution, count coincidence, response to irregular particles, and inlet efficiency, experimental studies are generally required. Liu et al. reported on the evaluation of several commercially available white-light counters using monodisperse spherical particles. Wen and Kasper and Liu and Szymanski evaluated the counting efficiencies of several commercial OPCs. A novel technique to determine the OPC response to irregular coal dust particles has been developed by Liu et al. Marple and Rubow made use of inertial impactors to obtain aerodynamic particle size calibration of the OPCs. Recent work mostly involves the evaluation of laser OPCs. Comprehensive discussions on the principle and application of the OPC may be found in the papers by Willeke and Liu, Knollenberg and Luehr, and by Gebhart et al.

Recent developments in OPCs are to increase the coincidence level while keeping high sampling flow rate, to measure the refractive index, and to determine the particle shape using the scattering intensity from multi-angle light scattering. A review of recent developments was presented at the 5th International Congress on Optical Particle Sizing.

### 3.4 Aerodynamic Particle Sizer and Aerosizer

In addition to direct light scattering measurement described above, light scattering can also be used in combination with other measurement principles to extend the measurement capabilities of the light scattering technique. An example of this is the use of an accelerating nozzle in combination with light scattering measurement.

![Schematic diagram of the APS described by Agarwal et al.](image-url)
Figure 7 shows a schematic diagram of a commercially available aerodynamic particle sizer (APS) described by Agarwal et al. In this instrument, the particles are accelerated through a small nozzle to different speeds. The larger the particle size, the lower the speed of the particle due to particle inertia. The particle velocity at the nozzle exit is then measured by detecting the time required to pass through two laser beams with a fixed separation to provide a measure of particle size. This principle enables the “aerodynamic size” of the particles, in the size range 0.5 to 30 µm, to be measured, which is related to the settling speed of the aerosol and to particle deposition in the lung. Calibration studies on the APS have been reported by Chen et al. and Baron.

Current developments in APS include an ultraviolet (UV) pulse laser to detect the viability of bio-aerosol, and a high energy laser, such as an Nd:YAG (neodymium : yttrium aluminum garnet) laser, and mass spectrometry for in-situ particle composition measurement.

A second commercial aerodynamic sizing instrument, the Aerosizer, operates under the same time-of-flight principle as the APS. One significant difference is that particles are accelerated at sonic flow through a critical nozzle in the Aerosizer whereas subsonic flow acceleration is used in the APS. The Aerosizer is capable of measuring particles in a wider size range (0.5 to 2000 µm) and higher concentration (up to 1100 particles cm\(^{-3}\)) than the APS. However, the calibration curve for particle size is strongly dependent on particle density. Cheng et al. calibrated two Aerosizers using uniform-sized spherical polystyrene latex particles (PSL) and glass beads and with nonspherical natrojarosite particles.

### 3.5 Electrical Low Pressure Impactor

By combining a conventional particle size classification method, e.g. the cascade impactor, with a direct reading particle detector, a near real-time particle size distribution analyzer can be constructed. Traditionally, the operation of cascade impactors involves depositing particles on a substrate and weighing the substrate before and after each sampling period. Consequently, traditional cascade impactors, such as the micro-orifice uniform deposition impactor (MOUDI), are not considered as direct-reading instruments. By installing a quartz crystal sensor on the collecting stages of the cascade impactor, it is possible to perform nearly real-time size distribution measurement. A commercial instrument, the quartz-crystal microbalance (QCM), has been developed making use of this principle. Two drawbacks of this technique are that the crystals need frequent cleaning and the concentration range is limited in order to avoid overloading the crystal stages.

This is partially remedied by the recent development of an electrical low pressure impactor (ELPI), shown schematically in Figure 8. The ELPI make use of a diffusion charger to charge the aerosol particles electrically. The charged particles are then impacted on the collection stages equipped with a current-detecting electrometer. The impactor stages provide the cut-size information and the currents provide the particle concentration information. The parallel current measurements allow a fast response compared with the DMPS and reduced maintenance compared with the QCM cascade impactors.

### 3.6 Phase Doppler Analyzer

The optical techniques described above involve extracting aerosol from the environment and transporting it to a sensing zone for measurement. In-situ techniques, often optically based, are noninvasive and measure aerosol in its natural state without extractive sampling. The noninvasive measurement is accomplished by locating the sensing volume external to the instrument, thereby eliminating the need for extractive sampling. The techniques are most suitable for measuring aerosols in hostile environments of extreme pressure and temperature ranges, and in reactive or corrosive environments.

Rader and O’Hern summarized the techniques in a review paper. They classified the techniques into the following major categories: single-particle counters that
are intensity-based, phase-based, or imaging; and ensem-
ble techniques of particle field imaging, Fraunhofer
diffraction, or dynamic light scattering. To determine
the particle size, single-particle counters measure the
scattering behavior of an individual particle as it passes
through a well-defined sensing zone formed by two cross-
ing laser beams, while the ensemble techniques analyze
the collective scattering of a large number of parti-
cles. They can be used to measure individual particle
sizes from about 0.25 to above 1000 μm, concentra-
tions as high as 10⁶ particles cm⁻³, and speeds in the
kilometer per second range. With the ensemble tech-
niques, particle mean diameters as low as 0.01 μm can be
measured.
An example of a single-particle counter based on
the phase Doppler principle is shown in Figure 9. The
principles of a phase Doppler particle analyzer
(PDPA) were described in the paper by Bachalo and
Houser. The system consists of a laser and transmit-
ting optics, and a receiver optics package with multiple
photo-detectors to measure the spatial and temporal
frequency of the Doppler-shifted light scattered by indi-
vidual particles passing through the measuring volume.
The spatial frequency gives a measure of the parti-
cle diameter, refractive index and receiver geometry,
while the temporal frequency gives a measure of the
particle velocity. A commercial instrument gives the
information on the recent development of a phase Doppler particle-sizing velocimeter can be
found in a special issue of Particle and Particle Systems
Characterization.

4 TOTAL (INTEGRAL) CONCENTRATION
DETECTORS

Integral concentration detectors are those that can be
used to measure some integral parameters of an aerosol
over its entire size distribution, such as the total number or
mass concentration or total light scattering or extinction
coefficients. Several of the more widely used instruments
are described below.

4.1 Condensation Particle Counter
The CPC, or condensation nucleus counter (CNC), is
widely used to measure particles in the diameter range
from approximately 0.005 to 1.0 μm. The instrument
operates by passing the aerosol stream through a vapor-
supersaturated region produced either by the adiabatic
expansion or direct contact cooling to cause the vapor
condensation on the particles. The particles are then
grown to a size where they can be detected optically by
light scattering. Recent advances include the development
of a continuous flow, direct contact type CPC and
the mixing of a hot vapor stream and a cool aerosol stream
to achieve a supersaturation condition.

A schematic diagram of a commercially available,
continuous flow CPC is shown in Figure 10. In this
instrument, butyl alcohol is used as the working fluid. An
air stream is saturated with this vapor in a saturator kept at
35 °C. The subsequent cooling of this alcohol-vapor laden
air stream in a thermoelectrically cooled condenser tube
kep at 10 °C produces the required supersaturation for
the vapor condensation on the particles. Particles emerg-
ing from the condenser tube at a size of approximately
12 μm are then detected optically by light scattering.
For low particle concentrations, individual particles are

---

Figure 9 Schematic diagram of the phase Doppler analyzer.

Figure 10 Schematic diagram of the CPC.
counted. Above a particle concentration of 1000 particles cm\(^{-3}\), the total light scattering from the droplet cloud is detected in a “photometric mode” to measure the total particle concentration. The concentration range of the instrument is from less than 0.01 particles cm\(^{-3}\) to more than 10\(^6\) particles cm\(^{-3}\).

Detailed calibration studies of the CPC have shown that below a particle size of 0.005 \(\mu\)m the response of the instrument begins to drop off as a function of particle size.\(^{63–71}\) The counting efficiency decrease can be attributed to particle loss in the flow passages in the instrument due to diffusion and the lack of 100% activation due to inhomogeneous vapor concentration distribution in the condenser. By introducing clean sheath air around the aerosol stream in the CPC, Stolzenburg and McMurry\(^{67}\) were able to increase the counting efficiency of the instrument to over 70% at a particle size of 0.003 \(\mu\)m. Figure 11 shows the details of such a sheath air CPC UCPC. Wilson et al.\(^{72}\) using a similar design have developed a low pressure CPC for stratospheric aerosol measurements. Niessner et al.\(^{73}\) have shown that by changing the supersaturation ratios in steps, the dependence of particle size on critical supersaturation for vapor condensation can be used for size distribution measurement.

### 4.2 Light-scattering Photometers and Nephelometers

For atmospheric studies, the total light scattering coefficient of the airborne particles is important as it is related to atmospheric visibility or visual range. Measurement of the total light scattering coefficient is usually made with a photometer or integrating nephelometer. For aerosols that differ only in concentration and with the same size distribution, the integral light scattering measurement can be converted to mass concentration. Examples of such a correlation between total scattering and atmospheric mass concentration are given by Waggoner and Charlson.\(^{74}\)

In the integrating nephelometer, shown schematically in Figure 12, the particles are illuminated in a sensing volume of approximately 1.0 L and scattered light from the particles reaches the photoreceptor at angles from 8° to 170° off axis. This simplifies the complex angular scattering relationship by summing the scattering over nearly the entire range of angles. Although the instrument was originally used to measure visual range, it has found its application in the study of the urban and rural atmospheric aerosol. In some cases, the scattering has been shown to be well correlated with the atmospheric mass concentration.\(^{74,75}\) The instrument is simple in construction and has been used in automobiles and aircraft for mapping the concentration of particles in the 0.1 to 1.0 \(\mu\)m range. These particles are chiefly responsible for degraded urban visibility. Some caution must be exercised when using the nephelometer in an environment with sooty particles since the scattering will
be attenuated because of light absorption. In this case the apparent concentration will be lower than expected.

Forward-scattering photometers, which employ a laser or incandescent light source and optics similar to dark field microscopy, have been commercially produced. A narrow cone of light converges on the aerosol cloud, but it is prevented from falling directly on the photoreceptor by a dark stop; only light scattered in the near forward direction falls on the receptor. The readout of these instruments is in mass or number concentration, but the calibration may change with composition and size distribution of the particles. Based on the solutions to Maxwell’s equations, forward scattering photometers are, however, less sensitive to the change in the refractive index of particles than are photometers at other commonly used sensing angles such as 30°, 45°, or 90°.

A forward-scattering photometer (45°−95°) was developed as a passive personal monitor for airborne particles. This instrument displays the real-time particle mass concentration for time intervals as small as 10 s and calculates time-weighted averages (TWAs) for up to a full shift in a workday for display or readout.

### 4.3 Quartz-crystal Microbalance and Surface Acoustic Wave Microbalance

Several sensors for near real time mass concentration measurements have been developed. By depositing the particles on a quartz crystal the natural vibrating frequency of the crystal can be affected and used as a measure of the deposited particle mass. The deposited particle mass is proportional to the frequency shift. The particle deposition can be achieved either by electrostatic precipitation or by inertial impactation. The sensitivity of the QCM is approximately 10⁸ Hz g⁻¹, which corresponds to a frequency shift of 1 Hz for a 10 MHz AT-cut quartz crystal. Figure 13 shows a schematic diagram of a battery operable piezoelectric microbalance for respirable aerosol detection. The instrument incorporates a respirable impactor at the inlet to remove the nonrespirable particles, allowing the respirable particles to be deposited by electrostatic precipitation on the quartz crystal for measurement. The instrument can measure particle concentrations in the range of approximately 0.05–5.5 mg mL⁻¹.

A new development in QCMs enables the mass sensitivity to be significantly increased relative to the ones using AT-cut crystals. By modifying the quartz crystal and applying an electric field between two electrodes on the same surface (instead of through the crystal thickness) several micrometers apart, the mode of excitation results in a natural frequency of up to 300 MHz. The vibration on the same surface is called the surface acoustic wave (SAW) mode. The mass sensitivity of the SAW devices can be up to 10¹⁰−10¹¹ Hz g⁻¹.

### 4.4 Tapered-element Oscillating Microbalance

Recent advances in the vibrating mass sensing technique include the use of a low frequency vibrating mass in the form of a hollow tapered element coupled to a filter collector or impactor. The operation principle of the tapered-element oscillating microbalance (TEOM) is the same as for the QCM. Instead of relying on the natural frequency of quartz crystal, the vibration of the hollow tapered element is initiated and maintained by an electronic feedback system. The oscillation of the tapered element is then monitored by a light-emitting diode and phototransistor aligned perpendicularly to the oscillation plane of the tapered element. Figure 14 shows a typical arrangement for a TEOM. The aerosol stream is drawn from the ambient air and passed through a filter installed on the top of the tapered element. The collected particle mass is then inferred from the frequency difference before and after each sampling. Unlike QCMs, the collected particle mass is not directly proportional to the frequency shift. It is proportional to the difference of the inverse square of frequencies before and after sampling. This design extends the measurement range of the technique to mass concentration levels in the gram per cubic meter range. The filter can usually hold particle masses up to 2–6 mg. The application of the technique to particle measurement in high-temperature and high-pressure gas...
streams of the pressurized fluidized bed combustor has been reported by Wang.\(^{(82)}\)

5 MONODISPERSE AEROSOL STANDARDS

In order to correctly interpret the experimental data and to obtain the highest possible accuracy from a given instrument, a detailed calibration of the instrument with a monodisperse aerosol is required. In some cases, the availability of these aerosol standards has made it possible to develop new aerosol sensors for which the underlying theory is not well understood. Figure 2 shows some of the available monodisperse aerosol standards for calibrating the direct reading instruments.

5.1 Electrospray Aerosol Generator

Figure 15 shows a schematic diagram of the electrospray aerosol generator.\(^{(83)}\) The spraying chamber is in the point-to-plate configuration with the capillary tube facing the plate. An orifice is located on the center of the plate, allowing the produced particles to enter the neutralization chamber. A coaxial tube allows CO\(_2\) to flow as a sheath surrounding the capillary tube for suppressing possible corona discharge. The compressed air is supplied from the top of the chamber in order to transport the particles through the orifice. The liquid is fed from a syringe driven by a syringe pump. The flow rate is controlled by a programmable syringe pump. Once the droplets are produced, they are transported into the neutralization chamber quickly for neutralizing the highly charged droplets produced by electrospraying.

A negative high voltage is applied to the plate and the neutralization chamber. The capillary tube is connected to an electrometer which is used to measure the spraying current. The size of the produced liquid droplets is further reduced by the evaporation process. Using this technique, monodisperse aerosol particles in the range 3 nm up to 1 \(\mu\)m have been successfully produced.

The electrospray can also be used to aerosolize colloidal particle suspensions. For example, PSL and colloidal gold particles have been successfully produced using the electrospray. The droplet sizes produced by the electrospray are small compared to those produced by mechanical atomization techniques. It therefore produces much smaller residue particles in spraying the colloidal suspensions.
5.2 Vibrating Orifice Aerosol Generator

The vibrating orifice aerosol generator (VOAG), shown schematically in Figure 16, was developed by Berglund and Liu.\(^{(84)}\) The generator is based on the instability and uniform break-up of a liquid jet under a uniform, periodic mechanical disturbance. The generator is composed of a droplet generation and dispersion system and an aerosol dilution, neutralization, and transport system.

To generate an aerosol with this system, a solution of a known solute concentration is supplied to the droplet generator by a syringe pump. The liquid flows through a small (approximately 10\(\mu\)m) orifice in the droplet generator and is broken up into uniform droplets by the mechanical vibration produced by a piezoelectric ceramic. The uniform droplet stream is then quickly dispersed by a turbulent air jet to prevent droplet collision. The dispersed droplets are then mixed with a filtered dilution air to evaporate the solvent from the solution droplets. The aerosol is subsequently passed through a radioactive \(^{85}\)Kr neutralizer to discharge the electrostatic charges on the particles prior to using it as a calibration aerosol.

The diameter of the aerosol particles produced by the vibrating orifice generator can be calculated from the equation for the conservation of mass. The overall uncertainty of the calculated particle size is about 1%.

5.3 Electrostatic Classifier Aerosol Generator

For producing submicron monodisperse aerosol standards in the size range from below 0.005\(\mu\)m to 1.0\(\mu\)m, an electrostatic classifier aerosol generator has been developed by Liu and Pui.\(^{(85)}\) The method is based on the monotonic relationship between the electrical mobility of a singly charged particle and particle size. By passing aerosol with predominantly singly charged particles through the mobility classifier, a monodisperse fraction can be extracted according to electrical mobility. The generator, shown schematically in Figure 17, consists of a polydisperse aerosol generator, a \(^{85}\)Kr charge neutralizer, a DMA, and an electrometer current sensor.

To generate a monodisperse aerosol with this system, a polydisperse feed aerosol is first produced either by atomization or by a vaporization-condensation technique. The aerosol is then passed through the \(^{85}\)Kr charge neutralizer to obtain a Boltzmann equilibrium charge on the particles.\(^{(85)}\) For submicron particles, an aerosol in Boltzmann charge equilibrium will contain both positively and negatively charged particles of a low level charge. This aerosol is then classified electrostatically by the DMA to obtain a monodisperse, singly charged aerosol.

The electrical mobility of the extracted monodisperse aerosol can be calculated from the operating condition of the DMA.\(^{(85)}\) Knowing the aerosol mobility, the particle diameter can then be calculated. An accuracy of 2\% in the calculated particle diameter can be achieved from carefully measuring the aerosol and clean air flow rates in

![Figure 16 Schematic diagram of the VOAG.\(^{(84)}\)](image)
the DMA and the applied voltage on the central electrode
in the DMA.

By sampling these singly charged particles into a
Faraday cup (the electrometer current sensor) and
measuring the corresponding current flow, the particle
concentration can be calculated.

The electrostatic classification technique was used as
a secondary transfer standard for the certification of
the 0.1 µm standard reference material (SRM) by the
National Institute of Standards and Technology (NIST).
The method involved “calibrating” the DMA by two
established primary calibration standards 0.269 µm PSL
(NIST SRM 1691) and 0.895 µm PSL (NIST SRM 1690).
Once the flow rate and the voltage of the DMA were
adjusted according to the two primary standards, it was
then used to measure the 0.1 µm PSL for establishing the
0.1 µm SRM.

### 6 SUMMARY

Considerable advances have been made in recent
years in the development of direct-reading instruments
for analyzing airborne particles. Instruments are now
available to measure aerosol number concentration up to
10^6 particles cm⁻³, mass concentration up to 1000 mg m⁻³,
and size distribution over a particle size range of 0.003 µm
to over 100 µm. Advances in instrumentation are such that
many of the measurement problems that were considered
too difficult only 10 years ago can now be performed
routinely with good experimental accuracy.

With a wide array of available commercial instruments,
it is necessary for the practitioners to understand well the
operating principles of the instruments and the aerosol
system under study. Some of the criteria for selecting
an appropriate instrument include the particle size range
of interest; the system parameters to be studied, e.g.
mass or number concentration versus particle size dis-
tribution, aerodynamic property versus light scattering
property, etc.; and the cost and compactness of the
instrument. Several useful references can be used to
help select the appropriate instruments for the specific
applications. Pui and Swift provided a comprehensive
review of the available instruments, and the specifications
and commercial sources for these instruments. A detailed
state-of-the-art review of instruments of different prin-
ciples is contained in the book edited by Willeke and
Baron.

Figure 18 shows a flow chart for selecting a direct-
reading instrument for analyzing airborne particles.
The first step is to decide whether to perform an
integral concentration measurement or a complete
size distribution measurement. In principle, the inte-
gral concentration, i.e. mass concentration or num-
ber concentration, can be obtained by integrating
the size distribution over the appropriate size range. However, there are many compact, inexpensive instruments available for integral concentration measurement compared to the more sophisticated and expensive instruments for size distribution measurement. Considerable cost saving can be realized if an integral concentration detector is deemed appropriate for the application.

For mass concentration measurement, as required in many industrial hygiene applications, the particles may be directly captured on a surface for measurement by the quartz-crystal sensing technique or by the beta-attenuation sensing technique. These techniques generally require longer sampling time and frequent cleaning of the surface. A quicker method would be to measure indirectly the light scattering intensity of the aerosol and to infer its mass concentration through calibration. The accuracy of the technique depends on the measured aerosols having nearly the same size distribution and differing only in concentration.

For number concentration measurement, as required in many cleanroom applications, two classes of instruments may be used depending on the size range of interest. For particle diameter less than 2 µm, several CPCs may be used. For particle diameter larger than 0.1 µm, a large array of white-light or laser OPCs may be used.

For size distribution measurement, the instruments are divided into two major classes depending on their measuring size ranges. For particles larger than 0.1 µm, the OPCs or the particle relaxation size analyzers may be used. The latter are capable of measuring the aerodynamic particle size, which is important for deposition studies in the respiratory system. For submicron aerosol, the high-resolution DMPS or the low-resolution diffusion battery and the electrical aerosol analyzer may be used. A number of special purpose instruments are also available for difficult applications. For example, the PDPA measures aerosol in its natural state without extractive sampling. The noninvasive measurement is

**Figure 18** Flow chart for selecting a direct-reading instrument for analyzing airborne particles. 

For number concentration measurement, as required in many cleanroom applications, two classes of instruments may be used depending on the size range of interest. For particle diameter less than 2 µm, several CPCs may be used. For particle diameter larger than 0.1 µm, a large array of white-light or laser OPCs may be used.

For size distribution measurement, the instruments are divided into two major classes depending on their measuring size ranges. For particles larger than 0.1 µm, the OPCs or the particle relaxation size analyzers may be used. The latter are capable of measuring the aerodynamic particle size, which is important for deposition studies in the respiratory system. For submicron aerosol, the high-resolution DMPS or the low-resolution diffusion battery and the electrical aerosol analyzer may be used. A number of special purpose instruments are also available for difficult applications. For example, the PDPA measures aerosol in its natural state without extractive sampling. The noninvasive measurement is
accomplished by locating the sensing volume external to the instrument, thereby eliminating the need for extractive sampling. The technique is most suitable for measuring aerosols in hostile environments of extreme pressure and temperature ranges, and in reactive or corrosive environments. The cost of such a system, however, will be many times that of an integral concentration detector.

Instruments are also developed to meet specific applications. Examples include the development of a portable CPC for respirator fit testing, the adaptation of APS for bioaerosol/particle component measurement and the development of high flow rate laser particle counters for cleanroom applications. Computer direct-reading instruments have been developed with modern electronics and transducer technologies. Significant efforts have also been devoted to improve the software for on-line data reduction. These hardware and software developments will make the next generation of aerosol instruments more sensitive, accurate, compact and user friendly.

Aerosols and Particulates Analysis: Indoor Air

**REFERENCES**

Dust is a source of contamination of land, water and the atmosphere, and is of special concern owing to its trace metal content. There is a significant body of literature describing the use of deposited dusts as indicators of environmental pollution, particularly by trace metals. While several authors have identified the need for standardized guidelines on sampling techniques and on analytical procedures, few have addressed the problems in sufficient depth to produce such guidelines. Since some of the early papers on this topic, more is known about the chemical nature of dusts and the association of certain metals with components of the matrix. This information provides useful guidance on analytical techniques and methods for dissolution of samples.

In the analysis of trace elements in dusts, a prerequisite is to prepare a solution for analysis. A variety of methods have been used to digest dust samples for determination of trace metals, and this can make it difficult to compare the results from different studies. Whether total or available metal content is determined is just one uncertainty needing resolution. Time requirements range from 15 min to 24 h, and this is another variability that may make results incomparable, while the great amounts of acids and long digestion times may result in contamination. For over 20 years, microwave ovens have found increasing use and have been used to digest various kinds of samples, such as rocks, sediments, ores, soils, coal, fly ash, water, sludge and biological and botanical samples. This article describes the efficiency of various acids for the digestion of dust, both by traditional methods and using a microwave oven. The latter technique offers an advantageous route for the digestion of dust samples in preparation for trace metal analysis. Speed and good recovery coupled with less risk of contamination through the limited amounts of reagents required combine to make this an excellent choice in the suite of techniques for environmental analysis.

General reviews of analytical methods demonstrate the dominance of atomic absorption methods for the analysis of trace metals such as lead and cadmium in a variety of samples. This pattern is generally found for work on metals in dusts, with flame atomic absorption predominating for Pb, Cd, Zn, Ni and Cu. Other techniques have included neutron activation (NA) and inductively coupled plasma atomic emission spectroscopy (ICPAES). Polarography in the form of differential-pulse anodic stripping voltammetry (DPASV) is suitable for the simultaneous determination of trace quantities of Pb and Cd in dust. The method gives good reproducibility and has the added advantages of being relatively cheap, quick and simple. Interferences and means for overcoming their effects will be outlined. The aim of analysis of dusts is to represent environmental quality. This necessitates appropriate presentation of the data from the analysis, and some issues relating to this will be outlined.

Dusts will always present a potential route of contamination by trace metals and organic substances and the need for future work in this area will not diminish. Only by the application of good quality control, the use of reference materials and reliable techniques and an understanding of the significance of the results can confidence be placed in a useful approach to environmental quality assessment.

1 INTRODUCTION

A good understanding of the quality of the environment is a precursor to rational decision making for environmental management (Figure 1). A variety of indicators serve in monitoring environmental quality, and in recent years dusts have been popular environmental samples for study. As a first impression, the concept of analyzing dusts may appear naive, but for many years investigators have used this medium as a convenient indicator of pollution levels. Dust analysis continues to be attractive to environmental scientists, influenced no doubt by its ubiquity.
and hence apparent ease of sampling. Dust is, indeed, a common material throughout the environment, although the degree of accumulation and its composition depend on many variables, including weather conditions, building construction materials, traffic density and industrial activity.

The role of dust as a potential vehicle for the intake of trace metals by children, especially in their home environment, has prompted many studies on dust composition. Its relevance is identified, inter alia, in a US Statute\(^1\) following recognition by the US Congress of the following issues:

1. Low-level lead poisoning is widespread among American children, afflicting as many as 3 800 000 children under age 6, with minority and low-income communities disproportionately affected.
2. At low levels, lead poisoning in children causes intelligence quotient deficiencies, reading and learning disabilities, impaired hearing, reduced attention span, hyperactivity and behavior problems.
3. Pre-1980 American housing stock contains more than 3 000 000 tons of lead in the form of lead-based paint, with most homes built before 1950 containing substantial amounts of lead-based paint.
4. The ingestion of household dust containing lead from deteriorating or abraded lead-based paint is the most common cause of lead poisoning in children.
5. The health and development of children living in as many as 3 800 000 American homes is endangered by chipping or peeling lead paint, or excessive amounts of lead-contaminated dust in their homes.
6. The danger posed by lead-based paint hazards can be reduced by abating lead-based paint or by taking interim measures to prevent paint deterioration and limit children’s exposure to lead dust and chips.

Similar observations on the role of paint have been made elsewhere.\(^2\)

Most investigations on dust have been concerned with the lead content, with emphasis on sources from industry, traffic or paint. However, studies have included a broad spectrum of metals.

Careful sampling and analysis of dust are fundamental to any of these investigations, but the inhomogeneous nature of dust presents many problems to the investigator. Several of these aspects are covered in this article, with particular emphasis on obtaining data that are comparable with those from other studies and guidelines, such as exist. Clearly, the potential for harm depends largely on the bioavailability of the metals. Some studies have aimed at differentiating the available from the total metal content, and this emphasizes the care that is needed in comparing data from different studies.

### 1.1 What is Dust?

According to the International Union of Pure and Applied Chemistry (IUPAC), dust is\(^3\)

Small, dry, solid particles projected into the air by natural forces, such as wind, volcanic eruption, and by mechanical or manmade processes such as crushing, grinding, milling, drilling, demolition, shovelling, conveying, screening, bagging, and sweeping. Dust particles are usually in the size range from about 1 to 100 µm in diameter, and they settle slowly under the influence of gravity.

In the context of air pollution there is no definition of dust in the legal provisions of the UK Clean Air Acts. “Grit” is defined in regulations\(^4\) as “particles exceeding 76 µm in diameter”, whereas “fume” is defined in the Clean Air Act 1993 as “solid particulate matter smaller than dust”. Hence a legal interpretation may be that dust is particulate matter smaller than 76 µm but with a lower limit of 1 µm.

These categories are supported by other guidelines:

1. **grit**, which is defined as “particles of solid matter which are retained in a sieve of 75 µm nominal aperture in conformity with BS 410: 1986 of the British Standards Institution”;

---

**Figure 1** Understanding the quality of the environment is a precursor to rational decision making for environmental management.
DUST, MEASUREMENT OF TRACE ELEMENTS IN

2. **dust** is particles of solid matter which will pass through a sieve of 75 µm nominal aperture in conformity with BS 410: 1986;

3. **fume** is usually regarded as solid particulate matter smaller than dust, i.e. <1 µm in particle diameter.

Such a size limitation may be applied by those involved in air pollution control, but more general environmental investigations tend to follow a definition such as that in the Shorter Oxford English Dictionary:

Earth or other solid matter so contaminated as to be easily raised and carried in a cloud by the wind; any substance pulverized; powder. Often extended to include ashes etc. from a house.

Some authors use the terms “dirt” or “sediment” as synonyms for dust, but all are referring to the general heterogeneous mixture of particulate matter deposited on surfaces. Clearly, the sources contributing to deposited dust are legion, but Ferguson and Schroeder\(^5\) suggest that approximately 60% of house dust is non-organic in nature, and this probably contains most of the lead. Of the inorganic material in a cloud by house dust, 30–40% comes from soil, 25–30% from street dust and 1–2% from aerosol that has settled in the house. Figures 2 and 3 illustrate X-ray spectra of two particles in dust. The first particle in a sample from a home (Figure 2) may have come from paintwork, as suggested by the high titanium level. The second particle in a sample from a domestic garage (Figure 3) clearly has a different origin. Absolute specification of their sources cannot be given without an unambiguous indicator species being identifiable. This approach will be referred to again later in this article.

Ferguson and Ryan\(^6\) suggested that soil contributes more to larger than to smaller dust particles, and hence nonsoil particles probably contribute more to smaller dust particles. As around 50% of dust occurs as large particles (963–213 µm), soil is a major component of street dust. This was so for all cities studied, although the proportion was greater for some (75–90% for Halifax, Christchurch and Kingston) than others (60% in London and 57% in New York). Subsequently, Thornton\(^7\) claimed that there is no reliable experimental method by which to quantify the soil component of house dust.

Clearly, soil is one of the major components of dust, whether from within or outside buildings, but the distinction between whether an external sample is dust or soil is problematic. It may be argued that size is not the critical factor in the definition of both types of particulate matter. To some extent, the term dust is dependent upon the source of the sample, so those samples from the roadside or inside buildings are called dust. Further, soil is particulate matter which contains nutrients for plant growth; dust does not have this quality. Studies on the composition of soil in dust do not use this criterion.

This article is concerned with deposited dust collected from hard external surfaces and from inside buildings. Materials of an organic nature such as bacteria are not relevant to this article.

1.2 Define the Objectives

A variety of objectives have driven investigations involving dusts. These have included health risk assessment in domestic, workplace and general environmental settings. Other studies have focused on city-wide surveys...
and comparisons between cities. It is by no means certain that the design of the research programs has been properly based on achieving these objectives. A clear, precise definition of objectives makes the subsequent stages in an investigation capable of being designed efficiently, and ensures no wasted effort or wasted resources. It also makes it more likely that the results of the analysis will satisfy the requirements of the study on environmental quality.

Three broad objectives summarize the general reasons for carrying out dust analyses:

1. Investigations of the chemical and physical characteristics of dust, to determine factors such as its composition, content, solubility to certain solvents and size of particles.

2. General surveys of the distribution of trace elements in dust in certain areas, to elucidate the relationships between the trace element levels and factors such as traffic, road surface, meteorology. In this category the concerns are usually to evaluate the quality of the environment and to identify sources of pollution.

3. Evaluation of the quality of dust in relation to possible effects on health. Such studies often focus on the content of certain toxic metals in dust in areas where exposure of humans, and especially children, may occur.

The profile of an environmental issue which has often been claimed to be relatively neglected was raised following the publication of the House of Commons Environment Committee Sixth Report (1990). Indoor exposure to many air pollutants can often exceed outdoor exposures. The report notes that the relative neglect is because indoor pollution is often chronic and not directly or immediately life-threatening. Certainly this is true for pollution by metals in dusts, and there have been many studies looking at dusts collected within buildings, where there is greater potential for exposure of more sensitive subjects, namely children.

Organic material may be present in surface dust from a variety of sources, many of which have been listed in detail in the context of potential contamination of water through surface runoff. However, relatively few studies have examined the organic composition of surface dusts. Nevertheless, fine dust re-suspended from the road has been linked to ambient levels of polycyclic aromatic hydrocarbons (PAHs) in air, although there are suggestions that there are significant particle size implications.

A sequential consideration of the factors involved in the design of a dust measurement programme may follow the scheme in Figure 4. Many of these factors will be addressed in this article.

2 SAMPLING

Sampling is an essential precursor to analysis. The aim of sampling is to collect samples whose quality represents the quality of the whole. To achieve this, it is first necessary
for the sample to represent truly the temporal and spatial variation of the quality of the whole, and this requires consideration of the sampling locations and the time and frequency of sampling. A second prerequisite is that the analyte(s) of interest have the same values as in the original. Hence it is essential to consider methods of sample collection, transportation and storage, with implications for representativeness again, and also for avoiding contamination or analyte loss. Ultimately the results of analysis must be expressed and interpreted to relate to the objectives, as well as being comparable with other work. Elwood10 commented that relevance of environmental measures to the actual exposure of subjects is probably one of the most difficult aspects of environmental research. While some compromise is usually necessary, some of the sampling procedures are utterly irrelevant. In particular, he cited that dust samples taken from a roadside gutter rather than from a pavement or from under a carpet are of unlikely relevance to human exposure. He concluded that the need for rigor increases as a field is progressively explored. This rigor starts by clarifying the objectives and following a sequence such as that outlined in Figure 4.

One of the earliest dust surveys11 compared samples from urban and rural areas. Another study of similar date12 had the objective of producing a city-wide survey of external and internal samples. External locations were classified according to road type, distance from industrial source or other characteristics according to a specified scheme. Some locations were repeatedly sampled on a seasonal basis while others were selected to give wide coverage. A later city-wide survey13 included sampling at 2 × 2 km grid square intersections and subsequently on a 1 × 1 km grid.

As this program was concerned with background levels, no samples were collected within 20 m of busy roads, 10 m of building facades or 100 m of factories. However, Archer and Barratt12 had demonstrated that the impact of an industrial source could be identified within 400 m of the source (Figure 5). Clearly, the height of discharge of dust will have an influence on the distance of contamination, and hence on the area for study or exclusion, depending on the objective. An elegant demonstration of dust sampling around a source was given by Hutton et al.14 in relation to Pb and Cd from a municipal incinerator. Samples were obtained at varying distances along radii at 50° intervals from 0 to 90° in the downward area around the stack. Roadside sites were excluded from this sampling scheme. Unfortunately the report was marred by there being no description of the sampling procedure.

Where roadside contamination is of interest, the fundamentals of dispersion from low-level sources suggest that sampling within shorter distances may be more appropriate than when elevated sources are involved.

For example, Archer and Barratt12 noted the decline in Pb concentration on moving from the gutter to the pavement (Figure 6). Grottker15 reported that 95.85% of street dust solids were found within 0.5 m of the kerb (gutter section) and that larger particles were more predominant in this gutter section than in the asphalt section. In contrast, Hamilton et al.16 found that for heavily used roads, lead concentrations were uniformly distributed over all surfaces sampled. This, they explained, was due to the rapid speed of the vehicles resulting in the movement of many of the Pb-rich fine particles towards the side of the road, where “dilution” with soil-derived material gave an even distribution of Pb. At one site, however, these authors did find elevated levels of Zn and Cd in the gutter.

The uncertainty of spatial variations was a question raised by Archer and Barratt15 and discussed by Duggan,17 who recognized that it was a problem difficult to address. No apparent reason could be found for differences in pavement samples spaced about 40 m apart, although samples collected on a 10 m grid pattern within playgrounds did not show significant differences. Fergusson and Ryan18 reported that over a limited area, individual dust samples were reasonably representative of the area. For example, 10 samples collected 0.5 m apart and within a total distance of 5 m had a mean lead level of 3430 µg g⁻¹ and a standard deviation of 270 µg g⁻¹. Data were also presented for Cr, Cu, Zn

![Figure 5](image-url)
and Cd to demonstrate reasonable uniformity and to justify characterizing various cities by only two or three samples of dust. As these authors analyzed a wide range of elements (26) and found that the concentration of the major elements (Al, Cu, K, Mg, Ti) and several trace elements were similar, they suggested that this justified their approach. More work would seem to be needed in this area, for as stated by Hamilton et al.\(^\text{(16)}\) it is an implicit assumption in all studies involving metals in dusts that representative samples have been taken.

In the context of soil sampling, Allen\(^\text{(18)}\) noted that an investigator must allow for the inherent variability of soil samples. A high degree of spatial variability may exist over small areas and has been demonstrated by Ball and Williams.\(^\text{(19)}\) Often the extent of this variation is unknown beforehand and hence sufficient samples must be taken to obtain a reliable measure of it. The absence of any indications of site variability can make it difficult to assess the significance of change such as seasonal variations that may be sampled by the data. Allen suggests that in practice between 5 and 10 replicates should be regarded as a minimum. However, if it is desired to estimate site variability with the same precision as might be obtained under more uniform laboratory conditions, at least 20 samples might be required.

By comparison, the scientific rigor usually applied to soil studies has often not been applied to dusts. Views on the numbers of samples required to produce meaningful results for dusts are as varied as the views on other aspects of dust sampling and analysis. Duggan\(^\text{(20)}\) recommended that a considerable number of samples was necessary owing to the large spread of values expected. This broad spread was demonstrated by data in one of the largest of the early studies,\(^\text{(12)}\) with typical ranges from a single city being reported as in Table 1.

In contrast, however, Ferguson and Ryan\(^\text{(6)}\) compared pollution in six cities by taking two dust samples from each and three from a seventh. Each sample was obtained from an area not greater than 1 m\(^2\). They noted the need for representative samples and commented that while few samples were taken, the “similar” concentrations for the major elements (e.g. Al, Cu, Na, K and Ti) and a number of trace elements suggested that the samples were reasonably representative. While this was true for some of the metals examined, close inspection reveals that some variations were wide by the standards of other studies. Thus, for example, lead levels ranged from 2008 to 4053 ppm in one city and from 887 ppm to 1.07% in another. Few other studies have relied on such small sample populations. Duggan\(^\text{(17)}\) explored in more detail the random variations over short distances. Repeated systematic sampling within school playgrounds (total area 5000 m\(^2\)) demonstrated wide ranges and standard deviations, but no significant difference between the three means on the three occasions. He concluded that despite sharp variations in concentrations over fairly short distances, valid results could be obtained by taking a comparatively small number of large-area samples, 5 m\(^2\) being indicated. While this modified view on sample numbers lends some support to the approach taken by Ferguson and Ryan, their sampling area of less than 1 m\(^2\) is small.

While there appears to be some doubt about the validity of using limited numbers of samples for wide-area and even city-wide studies, investigations of specific

sources clearly require more samples over a limited area. Thus Hutton et al.\textsuperscript{(14)} sampled at 15 points between 0.15 and 5 km along 15° radii between 0 and 90° in the downwind direction from an incinerator. Schwar and Alexander\textsuperscript{(21)} collected 5–12 samples in a “corridor” close to the external face of school buildings, while Rundle and Duggan\textsuperscript{(22)} collected 7–17 samples in each school playground. Over 600 samples (internal and external) collected over a long period of time within a 400 m radius of a major lead-using works were considered by Archer and Barratt.\textsuperscript{(12)}

The availability and cost of analytical facilities may determine the upper limit of the number of samples. One solution to the difficulty of analyzing large numbers of samples involves bulking, in which individual samples are combined to give a composite mixture. This method may give a satisfactory mean value, but conceals any site variability. The number of individuals making up the composite sample determines the validity of the mean. Allen\textsuperscript{(38)} cites that in variable soils even 30 individual samples may not be sufficient. Bulking procedures must be standardized by taking samples of equal volume from similar situations. Davies et al.\textsuperscript{(23)} used composite samples comprising 25 subsamples from pavements and roads. The subsamples were collected over an unspecified area but outside individual houses under investigation. One form of bulking may be regarded as sampling dust by sweeping a relatively large area. This approach was advocated by Duggan,\textsuperscript{(17)} who indicated 5 m$^2$ as appropriate, whereas Schwar et al.\textsuperscript{(24)} swept areas of 1–5 m$^2$ to help overcome problems of localized spatial variation.

### 2.1 Collecting the Sample

Implicit in this last reference is sweeping as a sampling technique. It is one of several options available, although none is without its problems.

There are recommendations of standard methods for the collection of dustfall\textsuperscript{(25)} and suggested guidelines for assessing nuisance from deposited ambient dust.\textsuperscript{(26)} Similarly, standards for collection of dust from flue gases\textsuperscript{(27,38)} have been adopted and followed for many years. No standard guidelines exist for deposited dust. Thus, as with many other aspects of dust analyses, the variety of methods used make it difficult to compare results and this problem is compounded by the failure of many to give details of procedures used in their work.

In general, sample collection methods may be grouped as brushing or vacuum methods. Further dividing these options into areas of applicability\textsuperscript{(20)} suggests

- single samples from vacuum cleaners for household dusts
- sweeping settled dusts from internal surfaces using a soft brush and thin card and storage in a self-sealing plastic bag
- bulked external samples collected with dustpan and brush.

Brushing involves using a soft brush to sweep dust from hard surfaces directly into plastic containers or on to paper and thence into containers or plastic bags. The need to avoid cross-contamination from the brush cannot be overemphasized. It is perhaps for this reason that some investigators prefer to use a spatula, which is also advantageous for damp samples. Suction techniques are another option, often using adapted domestic vacuum cleaners with collection of material on cellulose filters in an appropriate holder. Yet another option involves the use of moistened wipes to collect dust from surfaces, including hands.\textsuperscript{(30,31)} The defined sampling area is wiped with a single, opened, premoistened tissue, which is then placed in a clean, labeled, self-sealing plastic bag. The person sampling wears polyethylene gloves and a standard procedure is followed throughout.

Fergusson and Schroeder\textsuperscript{(32)} gave one of the more detailed descriptions of sampling and suggested collection by suction (using a small diaphragm pump with vacuum of 27 kPa) from an area of 0.25 m$^2$ carpet on to glass-fiber filters held at 6 mm above the carpet. Another detailed description included an assessment of collection efficiency.\textsuperscript{(33)} A different approach involves taking samples from the dust bag of domestic cleaners as included in the list above. This option was used, for example, in the Omaha childhood blood and environmental lead study\textsuperscript{(34)} and in a national survey in the UK.\textsuperscript{(35)} Implicit in all of these studies is the assumption that representative samples have been taken and that the approach has been standardized. Some claim to have done this.\textsuperscript{(36)} There is also the issue of comparability, addressed by Archer and Barratt\textsuperscript{(12)} in a matched set of brush and vacuum samples collected at each of 50 sites within a single office building. Their results were as set out in Table 2.

The results suggested to these authors that suction collected small particles such as fibers that effectively diluted the lead concentration, but more significant was the conclusion that this was an important area for further

work on sampling methodology. It is regrettable that part of a national survey of house dusts used techniques different from many others, and notably involved samples collected by both vacuum and brush techniques without confirming comparability.\(^{(23)}\)

### 3 SELECTION OF ANALYTICAL METHODS

Measurements of toxic metals such as lead and cadmium in dust are necessary for their hazard evaluation and also for the identification of their natural and anthropogenic sources. Reliable, convenient and economic, sensitive analytical methods play an extremely important role in determining the content of toxic metals in dust. The options for sample analysis are varied and published descriptions of methods are sometimes full of detail and sometimes too brief to repeat. Some of these procedures are presented in Figure 7.

There are many possibilities in each step of the sequence, and several steps may be interchanged or associated. However, the first stage invariably involves preparing the sample in a form suitable for the subsequent analysis. This preparation stage will depend somewhat on the analytical method to be used later.

#### 3.1 Particle Size

The inhomogeneous nature of dust was highlighted as a problem in the Introduction, and this is of no greater importance than in the context of particle size. The variation in metal concentration according to particle size may be seen by a cursory glance at the data for dusts collected from around an incinerator as summarized in Table 3. Notice that these data refer to “levels” expressed as micrograms per gram of trace metal measured in the sample. There are other options to consider, as will be outlined later.

\(\sigma = 113.5, \sigma = 2.13, \sigma = 115.6, \sigma = 0.76, \sigma = 219.0, \sigma = 1.45\)

\(\sigma = 203.7, \sigma = 1.39, \sigma = 181.7, \sigma = 0.97, \sigma = 1875, \sigma = 1.18\)
These observations are reflected in the wider literature. Ferguson and Ryan\(^{\text{16}}\) examined nine particle size fractions in the range \(33 \pm 8\) to \(963 \pm 38 \mu\text{m}\). They found that the amount of each element in each size fraction decreases with the particle size because of the decline in the amount of dust in the smaller size fractions. Typically, \(38–51\%\) of the amounts of all elements for all samples occurred in the coarse fraction, defined as \(213–963 \mu\text{m}\). However, for most of the elements, their concentration increases with decrease in particle size, although the extent to which this occurred varied considerably from site to site. This distinction between amount and concentration will be developed later in this article in the context of levels and loadings of metals.

The significance of the particle size effect in terms of environmental effects includes the greater contamination of storm-water sediments through runoff flushing the finer particles into the drainage systems, and the greater risk of contamination of children’s fingers leading to a greater risk of elevated body burdens of lead. From the analytical point of view, however, the problem is one of selecting a representative sample of the inhomogeneous mass.

The first step may be to reduce the sample bulk. Traditionally, mixing, heaping and quartering the air-dried sample has been the approach. The two opposite quarters are mixed and the process repeated to give the required sample size. It is usual to pick out large stones before proceeding with this process. For dusts, it seems unlikely that bulk reduction will be necessary unless a large cumulative sample is obtained. However, even if not reduced in bulk, the sample must be brought to a relatively homogeneous state by thorough mixing before being treated further.

The next problem concerns taking a specified size fraction for analysis or grinding the whole. Clearly if the latter route is chosen, care to avoid contamination of the sample, such as from cadmium in pigment of plastic grinding equipment, or to avoid differential loss of fine dust is essential. Hamilton et al.\(^{\text{16}}\) stated that there was some evidence that grinding increases the measured metal level, presumably because there is a greater surface area exposed which makes metal extractions easier. This statement contradicts evidence presented by Jones and area exposed which makes metal extractions easier. This metal level, presumably because there is a greater surface

---

**Figure 8.** The exchangeable fraction represents the surface-bound material, which is readily subject to sorption and desorption. Next, the carbonate phase represents moderate availability, which term also describes the subsequent fraction known as the Fe–Mn oxide phase. Some have further subdivided this latter phase according to the strength of adsorption to the Fe–Mn oxides. One extraction sequence for measurement of metals in these fractions of dusts is set out in Table 4.

3.2 Sample Decomposition and Dissolution

This stage of sample preparation is an important area of trace analysis. Its aim is to present the sample to the analytical instrument in a form suitable for the analysis, and usually this is in the form of a particle-free aqueous solution. Generally, this will involve destruction of organic compounds and dissolution of inorganic solids. However, some argue that in terms of potential for harm, the bioavailability is the appropriate measure rather than total content. The bioavailable fraction can be considered as that fraction of the metal content that can be absorbed into the bloodstream after ingestion of the dust. The physical and chemical properties of the dust and also the particle size will all influence the bioavailability.

3.2.1 Extraction

It is possible to extract metals selectively from the sample according to the degree of bonding to the dust matrix. Five fractions are often considered as reflecting the strength of bonding to the matrix, and hence the environmental availability.

A particularly detailed study of sequential extractions for the speciation of particulate trace metals in sediments was carried out by Tessier et al.\(^{\text{38}}\), who adapted methods of soil analysis. The concept of partitioning the solid material into specific fractions proposes that these can be selectively extracted with appropriate reagents. The five fractions selected are summarized in Table 4.

In sequential extraction, the exchangeable fraction represents the surface-bound material, which is readily subject to sorption and desorption. Next, the carbonate phase represents moderate availability, which term also describes the subsequent fraction known as the Fe–Mn oxide phase. Some have further subdivided this latter phase according to the strength of adsorption to the Fe–Mn oxides. One extraction sequence for measurement of metals in these fractions of dusts is set out in Figure 8.

Thus, there may be an “easily reducible” fraction (residue shaken with \(0.1 \text{ M NH}_2\text{OH} \cdot \text{HCl–0.01 M HNO}_3\) (20 mL), 30 min at \(20^\circ\text{C}\) followed by a moderately reducible fraction (residue shaken with \(1 \text{ M NH}_2\text{OH} \cdot \text{HCl–25% CH}_3\text{COOH}\) (20 mL), 4 h at \(20^\circ\text{C}\). general scheme continues with the organic fraction and concludes with the residual phase, which represents the environmentally immobile fraction.

For dusts from selected cities across the world, Fergusson and Ryan\textsuperscript{6} found that Pb, Zn and Cd showed similar extraction patterns (except for exchangeable Cd), the patterns for Mn and Fe were similar, while the extraction patterns for Cu were unique. Typically between 8.9 and 30.4% Cd was exchangeable whereas for the other metals the exchangeable component was relatively low (0–12.1%). Cu was present mainly in the organic fraction (32.6–74.3%) whereas the other metals were all present at less than 16.9% in this fraction. Pb and Cd were about equally distributed between carbonate and Mn–Fe oxide bound forms, while Zn was bound mainly to the Mn–Fe oxides. The major difference between the cities was for organic bound Cu, which related to the greater organic content of the dust in the bigger cities.

Gibson and Farmer\textsuperscript{39} reported broadly similar partitions for Pb, Zn, Cu and Cd across the phases with the exception of Zn, which they found in the greatest proportion (26%) in the residual phase. However, they reported that a common feature of the four elements was a decline in the relative significance of the residual fraction with increasing concentration. This was not unexpected in contaminated environments with high input fluxes of metals from polluting sources. Leaching of samples with hydrochloric acid (0.07 M) to represent human stomach acidity indicated that an average 41% Pb, 44% Zn, 28% Cu and 47% Cd was released. The results suggested that Pb, Zn and Cd associated with the exchangeable, carbonate and easily reducible fractions were quantitatively released by the dilute hydrochloric acid, with some additional zinc being removed from the moderately reducible fraction.

Tessier et al.’s method is that used most widely in studies on deposited dust, but many have debated its merits and sought improved approaches. One serious problem with Tessier et al.’s approach is that each fraction cannot be separated completely. So, for example, the sum of Pb and Cd in each fraction always exceeds the total amounts of Pb and Cd determined by digestion in mineral acids. Several of the alternative sequential extraction schemes have been discussed elsewhere.\textsuperscript{40}

### 3.2.2 Total Dissolution

Turning to the options for total destruction of the matrix, there is an extensive volume of literature on methods available for sample decomposition, which broadly divides into wet and dry techniques. In general terms, wet decomposition requires less equipment and there is less risk of volatilization and retention losses than for dry methods. Unfortunately, wet methods often require more reagents, more manipulations and hence present greater risks of contamination than dry decomposition. Dry methods require few reagents, little manipulation and bulky samples present few problems, although there is the volatilization risk which is particularly relevant to metals such as cadmium and lead.

There are, of course, inevitable exceptions. Alkaline fusion as a dry method requires more reagent, whereas wet digestion in the pressurized or microwave mode require little reagent, and such reagent is less contaminated. Such techniques do not appear to have found wide use in dust analyses. Reflecting on the relative merits of the options for sample destruction, it is perhaps no surprise that most investigators select wet methods. While it is hoped that reagent blanks and appropriate steps to control contamination and to purify reagents are included, it is unfortunate that the scant information on methods reported in many papers fail to mention these and other factors.

Table 5 illustrates a variety of techniques for sample destruction that have been used for dusts in the context of

</table>
a total or single representative concentration of the metal content. The gaps in the table indicate typical omissions of authors to give full details of procedures carried out.

It is clear from Table 5 that a variety of methods for sample dissolution have been used to produce a total or representative concentration of metal in dust. At a first impression, this range of methods appears to make comparisons suspect. Only one report describes dry decomposition, with dissolution of the residue in nitric acid.\(^{12}\) Losses of metal (Pb) in the dry decomposition stage were avoided by maintaining the temperature below 550 °C. The dry method was attractive in view of the large numbers of samples being processed. Of the wet decomposition methods available, Ferguson and Ryan\(^{6}\) found that acid extraction of samples (0.1–1 g) for 30 min in HNO\(_3\) (4 M, 10 mL) recovered more than 90% of lead and cadmium, and over 80% copper. These estimates were made by comparison with tests on samples completely dissolved in HF – HClO\(_4\), and agreed with previous work. Farmer and Lyon\(^{41}\) analyzed soils and dusts using a single extraction procedure involving acetic acid and hydroxylamine hydrochloride. They found that for soils it was over 90% effective in recovering lead; the results were usually 5–10% less than those obtained when 8 M HNO\(_3\) was used. Comparable studies on dusts were not quoted. The authors attributed the greater recoveries using HNO\(_3\) to its ability to attack organic matter, which in other studies they carried out with H\(_2\)O\(_2\). This reagent recovered less than 5% of dust and soil lead, and so they concluded that only minor amounts of lead were associated with the organic phase. It must be remembered that a “good” recovery for soils is not necessarily indicative of the behavior of dusts; the trace pollutant bound to the organic fraction of soils can be stripped off relatively easily. Many dusts may be siliceous while others contain aluminates, the exact chemical species depending on the origin of the components. Thus wet digestion without HF is unlikely to be complete, and should not be expected to give the total metal content. While some studies have demonstrated comparability of wet digestion with and without HF, it cannot be assumed that all dusts will behave similarly. Clearly, the varying nature of dust samples from different sites may cause recoveries to differ from dust to dust, unless a reliable “total” decomposition method is used. This implies that all except the last method in Table 5 are subject to uncertainty.

In the absence of a standard method for extracting lead from dust, Jones and McDonald\(^{37}\) compared the extraction efficiencies of four methods used in city-wide surveys in the UK. The authors did note that the method reported for samples from London was insufficiently detailed and precise to enable replication. From the methods tested, however, it was concluded that the differences in the analytical methods may account for the different lead values found in the different cities. Considerable caution was therefore recommended when comparing data from different surveys, and it was concluded that the problem will persist until there is agreement on a standard method of extraction of lead from street dust. This view echoed that of Archer and Barratt\(^{12}\) 7 years previously. Only a total digestion procedure will allow comparison of the results of analyses of different dusts with confidence.

The sample preparation methods considered so far are relatively simple, although up to 24 h may be needed for some procedures. The main problem is selecting a reagent that is effective in releasing the metal of interest in a form that represents the potential release in relation to the exposure of a subject in the environment. It may be argued that attempts to seek the “total” metal in the sample give the worst case of release into the environment. The methods considered so far, with the exception of HF digestion, should be called leaching methods. Virtually by definition, leaching methods give information on the way that metals are bound in the matrix, and by definition they do not give the total content.

### 3.2.2 The Microwave Oven Option

Microwave oven techniques have been used to digest various kinds of samples for many years.\(^{42–45}\) Compared with classical heating techniques, microwave methods are many times more efficient. The heating process is speeded up considerably and the sample preparation time can be reduced up to 10-fold. Two types of microwave digester are readily available, closed systems that use multiple pressurized containers, and open systems that focus the microwaves on the sample at atmospheric pressure. The conventional technique involves microwave heating of the sample with acid contained in a closed vessel comprising a body, cap and pressure release valve as illustrated in Figure 9. The whole of the vessel is constructed of Teflon\(^{9}\), which is relatively transparent to microwaves. A carousel within the oven holds several sample vessels. Heating causes a buildup of pressure within the closed vessel, and this facilitates breakdown of the sample owing to the higher boiling point of the reagents. This method has been used for digesting dust samples with different acids. Digestion in a microwave oven with different acids for various kinds of samples has been shown effective for Pb and Cd contents. The high pressure achieved in sealed vessels undoubtedly accounts for the effective digestion. The program used in the microwave oven method can bring the samples to 175–180 °C at a peak pressure of around 6 atm for most samples.

When HF has been used in the digestion procedure, it is essential to remove HF from the residue, otherwise
DUST, MEASUREMENT OF TRACE ELEMENTS IN

Figure 9 Microwave oven digestion cells. (Reproduced by permission from John Wiley & Sons.)

it will not only etch glassware and electrodes used in DPASV but also interfere with the determination of Pb by atomic absorption spectroscopy (AAS). A suitable removal procedure involves reaction of HF with boric acid according to a procedure we have reported elsewhere. To remove acids from open vessels, it is preferable to use low power, otherwise loss of elements may occur. The risk of explosion in a sealed vessel precludes the use of perchloric acid in the microwave oven. Similarly, the use of sulfuric acid is not recommended owing to its high boiling point with the consequent risk of damage to the Teflon vessels.

Three standard reference materials were used to validate this method of digestion (Table 6). Table 7 shows results by traditional digestion methods using different acids. Table 8 shows the recoveries using the microwave oven technique, and Table 9 compares the results by traditional digestion and the microwave oven method. It is clear that lower losses of metals occur in the microwave method, and when combined with the additional advantages of speed, lower acid requirements and lower blank values, the technique can be seen to be very attractive. However, there are limitations of the method. High-pressure digestion carries an inherent risk of explosion and there may be temperature limitations on the vessel used. In addition, multiple stage treatment is difficult when reagents have to be added during the dissolution procedure. Open microwave digestion systems overcome some of these problems, and can also handle larger sample sizes and avoid the cooling down period before pressurized vessels may be opened safely.

3.3.4 Residue Analysis

As commented upon previously, rarely is complete dissolution achieved with different acids. Even HF leaves a residue, particularly for river sediment, which has high silica content. X-ray spectrometry was used to check the residue to provide further evidence of digestion efficiency with different acids. This further demonstrated the utility of the microwave oven approach.

In summary, a microwave oven offers a route with many advantages for the digestion of dust samples. Speed and good recovery coupled with less risk of contamination through the limited amounts of reagents required combine to make this an excellent choice in the suite of techniques for environmental analysis. It is important to bear in mind, however, that although microwave digestion has these merits from the chemical analysis perspective, this may not be the conclusion in terms of assessing environmental health effects, for which biological digestion is more appropriate. This caveat has to be remembered in the context of assessing the significance of the analytical data at a later stage.

3.3 Metal Determination

A general review of analytical methods used throughout Europe⁴⁷ for principal pollutants demonstrated the dominance of atomic absorption methods for trace metals such as lead and cadmium, as Table 10 indicates. This distribution of methods is generally found in reports on subsequent work on metals in dusts, with flame atomic absorption predominating for Pb, Cd, Zn, Ni and Cu. Polarography was used for 10% of samples in studies on lead by Day et al.,¹¹ who found agreement with atomic absorption analysis better than ±3%. Hamilton et al. used the same two techniques, with polarography in the form of DPASV.⁴⁸ Other techniques have included NA analysis and ICPAES.

The literature on the use of DPASV for the determination of Pb and Cd in dust is limited; the method has been used primarily for the determination of metals in airborne particles and in soil. By comparison with AAS, DPASV offers rapid and simultaneous determination of Pb and Cd, and also Zn and Cu, if desired. A simpler treatment of dust samples and less expensive equipment are further advantages. The results of studies to optimize the conditions for dust analyses are summarized below.

3.3.1 The Effect of pH and Buffer System

It is clear from Figure 10 that for Pb and Cd the oxidation current peaks ([Pb²⁺] = [Cd²⁺] = 4 ppb) are independent of the pH of the solution in the acid range up to pH 6.
Above pH 6, the oxidation current decreases sharply and this is attributed to the formation of hydroxides.

In order to keep the ionic strength of solution constant, different supporting electrolytes are used. No significant differences have been found in the use of KClO₄, KCl, KNO₃, and sodium ethanoate. In practice, after digestion, HCl and NaOH were used to adjust the pH of the solution to neutrality, then 5 mL of 0.5 M ethanoic acid–sodium ethanoate buffer (pH 4–5) were added to keep the pH and ionic strength of the solution constant.

### 3.3.2 The Effect of Deposition Time on Peak Current

Prolonging the deposition time can increase the sensitivity of the stripping determination. However, this must not be too long, i.e. the concentration of the substances in the solution must not perceptibly decrease, or repeated results cannot be obtained. For Pb and Cd in the range 0.1–0.01 ppm, a deposition time of 2 min is enough to obtain a strong signal. For Pb and Cd concentrations of 0.01–0.001 ppm a deposition time of 5 min is suitable. Concentrations below 0.001 ppm demand a deposition time of 10–15 min in order to obtain a strong enough signal that is distinguishable from that of a blank solution.

### 3.3.3 Interference Studies

As noted previously, hydrofluoric acid offers the only sure method of digesting the whole of the dust matrix to release all trace metals. However, if dust samples are digested with this reagent, all residual acid must be removed subsequently, otherwise it will not only etch the glassware and electrodes but will also interfere with the determination of Pb and Cd. When the concentration of HF in the solution to be analyzed is below 0.04%, no obvious effects were observed. At a concentration of 0.16% the oxidation current for Pb increased more and more as the determination time increased, while the oxidation current for Cd decreased to a constant value. Boric acid can be added to react with HF to form tetrafluoboric acid.\(^{(49)}\) This method has been used in inductively coupled plasma emission spectroscopy (ICPES).\(^{(50-52)}\)

Up to 3.2% of H₂BO₃ has no effect on the determination of Pb and Cd by DPASV. The efficiency of HF elimination by boric acid in the solution of 0.40 ppm Pb and 4 ppb Cd is shown in Table 11.

Other potential interferences were studied\(^{(40)}\) by determining 0.04 ppm Pb and 0.02 ppm Cd in the presence of the following metal ions: Ag⁺, Bi³⁺, Ce³⁺, Co²⁺, Cr³⁺, Cu²⁺, Fe³⁺, In³⁺, Mn²⁺, Ni²⁺, Sn²⁺, Sn⁴⁺, Ti⁴⁺ and Zn²⁺. All were introduced at 4 ppm, which in most cases will be much higher than their concentration in the solution after digestion. Of these ions, only In³⁺, Sn²⁺, and Ti⁴⁺ showed significant interferences, as indicated in Table 12.

The available information for levels in dust suggests that In³⁺, Sn²⁺ and Ti⁴⁺ are present at very low levels, while the Cr³⁺ level of 20–200 µg g⁻¹ is beyond the interference range. Organic substances can also interfere in these determinations, but a technique for overcoming such problems uses the addition of potassium iodide.\(^{(53)}\) Adsorption of organic species such as surfactants may shift the peak potential in the anodic direction and may decrease the peak height. Removal or destruction of organic matter before the stripping analysis is desirable for samples rich in organic matter. Ultraviolet (UV) irradiation or ozone oxidation often accomplishes this, but both are time consuming. Other options have included ion-exchange columns in a flow-injection system, silica for adsorptive stripping voltammetry and poly(ester–sulfonic acid)-coated mercury film electrodes for DPASV. The use of KI not only reduces the effect of adsorption caused by some organics, but also gives the added benefit of enhancing the limit of detection (LOD) of Pb and Cd by DPASV. The effect is illustrated in Figure 11.

### 3.3.4 Limits of Detection, Accuracy and Precision

The LOD of the technique is dependent on the blank value, and is improved by purifying the chemicals used in the determinations. Using the voltammetric conditions

Table 15 Comparison of analytical results obtained by DPASV and AAS (n = 3–6)

A comparison between DPASV and AAS (Table 15) showed no significant difference (t-test) between the two methods.

3.3.5 Convenience

Determining Pb and Cd by AAS usually involves a dilute HNO₃ medium, because other Pb and Cd compounds, such as PbCl₂, CdCl₂, PbF₂ and CdF₂, are not as stable as Pb(NO₃)₂ and Cd(NO₃)₂. After digestion, concentrated acid must be removed by evaporation before analysis by AAS, whereas for DPASV the determination can be performed without evaporation. That makes the determination simple and rapid.

The effective conditions for the determination of trace metals in dusts using DPASV are summarized in Table 16.

4 DATA

On inspection of attempts to represent environmental quality by the composition of dusts, it is apparent that different authors have used different ways of representing analytical data.

Analyses of environmental samples may be carried out on the material as received, air dried or oven dried, but the final results are best reported on an oven-dry basis. This is usually equivalent to drying to constant weight at 105 °C. Many investigators have dried samples at 105 °C, while others dried at temperatures ranging from 30 °C (air drying) to 80 °C. Some equilibrated samples to constant temperature and humidity before weighing, while too many authors in the literature have failed to mention whether samples were dried and on what basis their results were presented; their data are therefore of limited value to others working in the field.

Most workers have expressed total or extractable concentrations in units of µg g⁻¹ or similar derivatives, although some use ppm. Some specify units of µg m⁻², as discussed later. As most studies involve many samples, the representative values may be quoted as arithmetic means (although in one case of two samples), as ranges, as geometric means or medians. Archer and Barratt demonstrated the positive skewness of the frequency distributions of lead concentrations in dusts,(12) with the log-normal pattern characteristic of many pollution data being evident in the figures presented. Similar frequency distributions have been found for cadmium, copper, lead, zinc and iron. It is clear from many observations that the use of median or geometric mean concentrations is a preferred representation of the "average" value of the metal concentration. It has been suggested that the median concentration for dust samples from several sites varies with time by less than 30% for all metals. Hence, although individual results may vary widely, as ranges indicate, the median of a number of samples can provide a reliable picture of metal distributions. There appears to be little significance in consistent ratios of geometric and arithmetic means claimed by several investigators, however. Doubt on this was cast by Archer and Barratt,(12) whose data indicated ratios varying from 1.36 to 4.95. The ratio is consistently much greater close to buildings, and even more inside buildings.

Figure 12 The incinerator and its surroundings.
Another issue concerns the concepts of *level* (in \(\mu g/NUL_{1}\)) and *loading* (in \(\mu g/m^2\)) that are used. Such different representations of data make comparisons difficult and may lead to different conclusions. This problem is best illustrated by an example involving two hypothetical samples. If sample 1 is collected from an area of 1 m\(^2\), while sample 2 is collected from 10 m\(^2\), the dust loading for both may be 1000 mg m\(^{-2}\) and both levels of lead 1000 \(\mu g/NUL_{1}\). However, the loading of lead for sample 1 is 1000 \(\mu g/m^2\) whereas that for sample 2 is 100 \(\mu g/m^2\). Depending on the method of presentation of the results, it may be concluded that the quality of dust expressed by the level of lead is the same, but it may be argued that in terms of the quality of environment area 2 is better than area 1.

Unfortunately, relatively few studies have acknowledged problems in data presentation such as that illustrated above, with few authors representing data as loading of trace elements. Those who use loading often fail to draw the reader’s attention to the significance of the terminology.

The difficulties may be illustrated using data from the investigation around the incinerator referred to previously. A representation of the source and its surroundings is given in Figure 12. The levels (i.e. concentrations) of Pb and Cd in different sized dusts were determined and gave the results shown earlier in Table 3. The results indicate that Cd levels in fine dust exceed those in coarse dust. Pb levels change more widely as particle size increases. Figures 13 and 14 represent cadmium and lead levels as isopleth maps, and while statistically insignificant on the basis of mean upwind and downwind results, it may still be seen from Figure 13 that the highest Cd level is in the downwind direction from the incinerator, about 2.25–2.5 km distant. This is the region where the greatest contribution by airborne dispersion from the incinerator to ground level concentrations was predicted under the most common stability category in the UK, namely class D. It is noteworthy that the same conclusion would be drawn from an analysis of the levels in the largest sized particles, although data from the mid-range size would suggest the greatest concentration elsewhere.

The levels of Pb shown in Figure 14 suggest no obvious relationship with the presence of the incinerator. Areas with the highest levels are in opposite directions, both upwind and downwind of the incinerator. Of special note

![Figure 13 Isopleths of cadmium levels in dusts collected around an incinerator. (Reproduced with permission from John Wiley & Sons.)](image)
is the observation that the highest levels occur in coarse dust fractions, suggesting that the incinerator is not the source of the metal in these samples, which were collected at greater distances from the stack. These results suggest that on the basis of pollutant levels, particulate matter released from the stack of the incinerator contributes to cadmium contamination of dust on the ground, although the contribution appears relatively small, with other pollution sources predominating. No impact on lead levels is indicated.

However, following the earlier logic, to evaluate the quality of environment it is necessary to consider the quantities of both metals and dust. A parallel for this is in relation to emissions to atmosphere, for which an assessment of mass emission may be more meaningful than the use of concentrations alone. Dust is only one environmental medium in which metals may be found, but in many respects it is unique. It is neither like air, which disperses widely in space, nor like water, in which dispersion within rivers, lakes and seas is possible. Since dust does not disperse uniformly, metals contained within the dust matrix cannot be expected to spread uniformly, even in the absence of a local source of pollution. A representation of the dust loading is given in Figure 15. The loading of a metal pollutant is a parameter to describe the quality of environment concerned with dust spread.

By comparing the spatial distributions, it was evident that the loadings of cadmium closely matched the locations for the highest loading of dust, whereas the highest lead loading was found at only one of these locations. The highest Cd levels are to be found to the northeast of the incinerator in the line of the prevailing wind direction, as discussed above. However the sites showing the highest Cd loading are located to the southwest of the incinerator, where great amounts of dust are deposited on the ground in the area of a discussed hospital. This is evident on comparing Figures 12 and 15. The highest Pb loading is northwest of the incinerator, at a car park and near a road junction. It was present in a great amount of fine deposited dust indicated in Figure 15. While some high Pb level sites are found elsewhere, the Pb loading is low because the amount of deposited dust is relatively low. The significance of these observations is that they demonstrate the care that is necessary in representing and interpreting data on environmental quality.
4.1 Relating Pollutants in Dusts to Sources

When applying dust data to environmental management, there is clearly a need to identify the source of the particulate matter. As the example of the incinerator demonstrated, simply identifying the presence of a contaminant does not associate it with the source.

Typical procedures involve:

- determining the topographic distribution to establish concentration profiles that relate sources and exposure points; this is similar to the approach around the incinerator;
- determining the relationships between elements, one of which may be a “tracer” characteristic of a specific source;
- determination of isotopic ratios to identify contributions from sources with different isotopic ratios.

One scheme for identifying further distinguishing features involves a sequence of steps (Figure 16).\(^{(34)}\) Scanning electron microscopic examination and energy-dispersive X-ray analysis of individual particles in each subsample follow the fractionation of each dust sample according to particle size, density and ferromagnetic characteristics. Figures 2 and 3 illustrated the results from...
such analyses. Hence the morphological and chemical characteristics of each sample to be determined can be related to those observed in the particulate matter from suspect sources. Associations of elements in specific particles may suggest the origin of the particle. For example, particles containing lead and bromine can be linked to car exhaust emissions,\(^{55}\) and lead to silicon ratios linked to soil, while lead to potassium can be linked to refuse burning.\(^{56}\) Other techniques for source characterization include the use of stable isotope ratio.\(^{57}\)

**4.2 Is the Environmental Quality of Dust Acceptable?**

In terms of cause and effect, an incident involving the release of a potentially harmful substance into the environment can be represented as

\[
\text{event} \rightarrow \text{impact on receptor} \rightarrow \text{consequences or effects}
\]

Land contamination, harm and loss of human life represent potential consequences at a site where the release has an impact. The cross-boundary dimension is represented by dispersion of particulate matter into the atmosphere, and subsequent deposition. The effects of an incident will depend on many factors including primarily the nature of the substance(s) concerned, its toxicity or other harmful effects, its pathways through the environment and its fate in the human body or other receptor. Clearly, biological responses depend on the duration of exposure and the ability of the substance(s) to reach target organs of the human body, for example, and all of these considerations are outside the scope of this article, which is concerned primarily with analytical methods for metals in dusts. However, some routes and their effects are shown in Figure 17. Clearly, in dealing with deposited dusts, this review is concerned with only a limited number of these routes of entry, and further is confined to human health effects. However, it would be remiss if awareness of the wider implications of dust contamination were not pointed out. Inhalation is an obvious route of entry as dust is transported through the atmosphere on its way to deposition. For airborne dusts there are well-established standards for health protection.

The lack of nationally agreed reference levels for judging the acceptability of trace metal concentrations in dust has been noted.\(^{58}\) Standards on pollution by trace metals in dust do not exist, although in their absence, tentative guidelines have been used by organizations...
such as the former Greater London Council. A guideline concentration for lead was adopted as 500 µg g⁻¹ to indicate the need for further investigation, while the level of 5000 µg g⁻¹ indicated a need for control action. The derivation and use of these guidelines are discussed further elsewhere.\(^{(39)}\)

A second proposal for guidelines for both soils and dusts starts from the assumption that a single value is inappropriate.\(^{(60)}\) Thus, a guideline in an area deemed acceptable in an industrial area would be unacceptable in a school playground. Blood lead is taken as the measure of tolerability and the guideline is derived from the model (Equation 1):

\[
S = \frac{|T/G^n - B|}{\delta} \times 1000
\]

where \(S\) is the guideline, a geometric mean concentration (micrograms of lead per gram of dust or parts per million), \(T\) is the blood lead guideline (micrograms of lead per deciliter of whole blood), \(G\) is geometric standard deviation of blood lead distribution, typically in the range 1.3–1.5, \(B\) is the background or baseline blood lead concentration in the population from sources other than soil or dust, \(n\) is the number of standard deviations corresponding to the protection required for the population and \(\delta\) is the slope of the response of the blood lead to dust lead relationship, with units of micrograms of lead per deciliter of blood increase per 1000 ppm increment of dust lead.

Examples of guidelines are shown in Table 17, although Wixson and Davies\(^{(60)}\) should be consulted for more detailed examples.

Deposited dusts will always present a potential route of contamination by trace metals and organic substances and the need for future work in this area will not diminish. Only by the application of good quality control, reference materials and appropriate techniques for decomposition of the matrix to match the objectives of the study can data be viewed with confidence and compared with such guidelines as currently exist.

In 1976, a Canadian group described in detail for the first time a new ion beam analytical method based on the elastic recoil of target nuclei collided with high-energy heavy incident ions. In this case, 25–40-MeV $^{35}$Cl impinged on a multilayer C or Cu (backing)/LiF or LiOH/Cu (30–150 nm)/LiF or LiOH and H, Li, O, and F recoiled atoms were detected. These exemplified the main characteristics of elastic recoil detection analysis (ERDA): its sensitivity to depth distribution and its ability to detect light elements in heavy substrates. In 1979, the use of megaelectronvolt energy $^4$He beams permitted the use of ERDA to be extended to depth profiling of hydrogen isotopes in the near-surface region of solids.

ERDA has rapidly been revealed to be an excellent alternative to resonant nuclear reaction spectrometry (see Nuclear Reaction Analysis) for hydrogen determination in solids. Despite its less advantageous performance with respect to its lower depth resolution, lower analyzable depth, comparable sensitivity, and more restricting irradiation and detection geometry, some ERDA features have made its development in ion beam analysis (IBA) laboratories worldwide easier; these are simultaneous access to $^1$H and $^2$H depth distributions, access to single-ended Van de Graaff accelerators compared with tandem accelerators or cyclotrons, and the ability to be combined with Rutherford backscattering spectrometry (RBS) (see Rutherford Backscattering Spectroscopy).

The development of detection devices and the analytical capabilities offered by high-energy heavy-ion-induced ERDA in material sciences for profiling light, medium, and high mass number elements give this method a wide area in which to progress. The main advantage of heavy-ion ERDA and quite unique feature among analysis techniques is the fact that all sample elements can be depth profiled in one measurement by single detector telescope. By means of Monte Carlo (MC) simulations, the interpretation and reliability of the results have increased greatly over the last few years.
1 INTRODUCTION

In 1976, L’Ecuyer et al.,(1) from the INRS-Energie Varennes (Québec), presented a paper that described in detail for the first time a new ion beam analytical method based on the elastic recoil of target nuclei colliding with high-energy heavy incident ions, in this case, 25–40-MeV $^{35}$Cl impinging on a multilayer C or Cu (backing)/LiF or LiOH/Cu (30–150 nm)/LiF or LiOH(1) The work exhibited two of the main characteristics that established the technique of ERDA: sensitivity to depth distribution and the ability to detect light elements in heavy substrates. The need to use high-energy heavy ions was a limitation to the development of this new analytical tool. In 1979, Doyle and Peercy published the first real example of the use of ERDA to determine hydrogen isotope depth profiles in the near-surface region of solids.(2)

At the same time, resonant nuclear reactions induced by energetic heavy ions were strongly promoted for the quantitative measurement of $^1$H, $^7$Li, $^{11}$B, $^{15}$N, and $^{19}$F in ions beams between 3 and 20 MeV were successfully shown to be very efficient for hydrogen depth profiling.(3–7) ERDA has been revealed to be an excellent alternative to resonant nuclear reaction spectrometry for hydrogen determination in solids. Despite its less advantageous performance with respect to lower analyzable depth, comparable sensitivity, and more restricting irradiation terms of irradiation and detection geometry, some ERDA features have made its use and development in IBA laboratories worldwide fast; these are simultaneous detection of not only $^1$H and $^2$H but also other elements, rapid development of detectors, and the great availability of small single-ended and tandem accelerators. As a result of detector development, especially in the case of TOF- and gas-ionization detectors, energies even below 10 MeV can now be used for high-resolution depth profiling.

In October 1996, Tirira, Serruys, and Trocellier, a group of French authors from Saclay published the first ion beam monograph entirely dedicated to ERDA. This book has been used as the basis for the technical part of the present article and also as a bibliographical source.

In the following, we establish the theoretical basis of elastic recoil phenomenon, describe the experimental configurations generally adopted for elastic recoil spectrometry, and illustrate the analytical capabilities of ERDA for quantitative measurements in solids. Section 2 is devoted to general considerations of elastic collisions induced by mega electron volt $^4$He and heavier incident ions in a hydrogenated material. Section 3 presents the practical characteristics of elastic recoil spectrometry in terms of irradiation and detection geometry, analytical performance, and data processing. Section 4 gives details of the main methodological variations from conventional ERDA using a single surface barrier detector and more recent experimental improvements. Section 5 is devoted to the use of high-energy $^4$He ions and heavy ions for carrying out light-element profiling in solids. Section 6 contains some application examples of ERDA in a wide variety of fields from polymer science to semiconductor or thin-film technology.(8–11)

The concluding section of this article attempts to focus on the relevance of ERDA in comparison with resonant nuclear reaction spectrometry and secondary ion mass spectrometry (SIMS) (see Secondary Ion Mass Spectrometry as Related to Surface Analysis) for hydrogen determination in the near-surface region of solids. It also indicates the major trends in ERDA development since 1997.

2 SCATTERING PROCESS AND CONVERSION OF ENERGY SPECTRUM TO DEPTH PROFILE IN ELASTIC RECOIL DETECTION ANALYSIS

2.1 Kinematics

When an incident ion (mass $m$) with kinetic energy $E_0$ (a momentum $P_0$) interacts with a target atom (mass $M$) at rest through a purely elastic collision, the application of the conservation principles for total energy and momentum allows us to write Equations (1) and (2) (Figure 1):

$$E_0 = E + E'$$

$$P_0 = p + p'$$

with $E$, $p$, $E'$, and $p'$ the respective kinetic energies and momenta of the scattered incident ion and the recoiled target atom. Introducing $\theta$ and $\phi$, the respective laboratory angles of scattering for $m$ and $M$ (Figure 1), we obtain Equations (3) and (4) given by

$$E' = K' E_0$$

where

$$K' = \frac{4 m M \cos^2 \phi}{(m + M)^2}$$

![Figure 1](attachment:image)

Figure 1 Schematic view of the elastic collision $m/M$. 

$\Omega (m, E, p)$

$\Omega (m, z, E_0, P_0)$

$\bullet (M, Z)$

$\bullet (M, E', p')$
and the angular relationship, Equation (5):

$$\tan \theta = \frac{\sin(2\phi)}{(m/M) - \cos(2\theta)}$$  (5)

If \( m > M \), as for example when \(^1\text{H}\) is the target atom and \(^4\text{He}^+\) is the incident ion, the incident ion cannot be scattered from its incident direction through an angle greater than \( \theta_{\text{max}} \). This value is directly derived from the above equations, Equation (6):

$$\sin \theta_{\text{max}} = \frac{M}{m}$$  (6)

For a \(^4\text{He}^+/^1\text{H}\) elastic collision, \( \sin \theta_{\text{max}} \approx 0.26 \) and \( \theta_{\text{max}} = 14.47^\circ \). For a usual recoil angle \( \phi = 30^\circ \, K' = 0.48 \), thus 2-MeV \(^4\text{He}^+\) gives protons recoiling from the target surface an energy of 960 keV.

The kinematics of the elastic collision is described in detail in two IBA handbooks by Chu and Tirira.

### 2.2 Cross Section

#### 2.2.1 Rutherford Scattering

The classical Rutherford formalism developed for a purely coulombian scattering leads to the well-known basic formula, Equation (7):

$$\left(\frac{d\sigma}{d\Omega}\right)^{\text{cm}} = \left[\frac{ze^2}{4E_0^{\text{cm}} \sin^2(\xi/2)}\right]^2$$  (7)

where \((d\sigma/d\Omega)^{\text{cm}}\) is the differential scattering cross section expressed in the center of mass system, \( z \) and \( Z \) are the respective atomic numbers of the incident ion and the target atom, \( e \) the elementary charge, \( E_0^{\text{cm}} \) the kinetic energy of the incident ion in the center of mass, and \( \xi \) the scattering angle in the center of mass.

In the laboratory system, Equation (7) becomes Equation (8):

$$\delta = \left(\frac{d\sigma}{d\Omega}\right)^{\text{l}} = \left(\frac{ze^2}{4E_0}\right)^2 \left[\frac{m}{M} + 1\right]^2 \frac{1}{\cos^3 \phi}$$  (8)

It is obvious that
- \( \delta \) exhibits a minimum value for \( \phi \approx 0 \);
- \( \delta \) tends to infinity when \( \phi \) tends to \( \pi/2 \); in this case, the projectile/target interaction cannot be described by the Rutherford model;
- \( \delta \) rapidly decreases as \( E_0 \) increases; and
- when \( M \gg m \), \( \delta \) is independent of the mass ratio.

In ERDA, Rutherford behavior is mainly observed for heavy-ion beams colliding with light target atoms (see Section 5) and for a \(^4\text{He}\) beam below 1 MeV.

#### 2.2.2 Non-Rutherford Cross Section

The Rutherford formula cannot be applied for elastic scattering/recoil spectrometry when the interaction potential between the incident ion and the target atom deviates from a pure coulomb potential. This can happen in two different cases. First, if the energy is high enough and secondly, in the low-energy case, if the two nuclei are screened by inner-shell electrons. The high energy at which elastic scattering/recoil cross sections begin to deviate from classic Rutherford behavior is called the threshold energy. It corresponds to the limit above which nuclear forces affect the interaction potential. Several authors have reviewed theoretical models combining a pure coulomb potential with a weak-perturbing nuclear contribution, as for example a Yukawa-like potential. Experimental measurements of the threshold energy have been made for several projectile–target nucleus couples and analytical formulations have been extracted.

Using \( R_0 \), the distance of closest approach as a free parameter, the threshold energy is expressed by Equations (9) and (10):

$$E_{\text{th}} = \left(\frac{ze^2}{2R_0}\right) \left(1 + \frac{m}{M}\right) \left(1 + \frac{1}{\cos \phi}\right)$$  (9)

where, for example,

$$R_0 = C_1 + C_2 (m^{1/3} + M^{1/3})$$  (10)

\( C_1 = 6.003 \times 10^{-1} \text{m} \), \( C_2 = 0.864 \times 10^{-15} \text{m} \), and \( 5.2 < (m^{1/3} + M^{1/3}) < 8.6 \) (after Räisänen). \( C_1 \) and \( C_2 \) are constants and \( m \) and \( M \) are the mass numbers. Applying this formalism, the threshold energy is 57.37 MeV for the couple \(^{35}\text{Cl} + ^{12}\text{C}\) and 469.60 MeV for the couple \(^{127}\text{T} + ^{16}\text{O}\).

In the case of heavy incident ions, the smaller cross sections due to the screening effect in low-energy scattering needs to be taken into account in the analysis. According to the analytical formula derived by Andersen et al., the deviation from the pure Rutherford cross section is 21.7, 10.4, and 1.5% for Cu recoils detected at 40° and ejected by 10 MeV \(^{197}\text{Au}\), \(^{127}\text{I}\), and \(^{35}\text{Cl}\) incident ions, respectively.

#### 2.2.3 \(^4\text{He}^+/^1\text{H}\) Collision

Historically, the scattering of protons by \(^4\text{He}\) target nuclei was first investigated in the range 1–20 MeV for \( E_p \). A phase shift analysis derived from quantum mechanics was thus applied to evaluate the cross section. The reverse collision can be treated by the same approach in the range 1–4 MeV for \(^4\text{He}\). The decomposition of wavefunctions in partial waves can be restricted...
to \(S_{1/2}\), \(P_{1/2}\), and \(P_{3/2}\) contributions to describe the scattering of \(^4\text{He}\) by \(^3\text{H}\). This method consists in determining the effective range, derived by Tirira and Bodart\(^{(25)}\) to extend previous phase shift studies.

The best set of theoretical parameters (scattering length and effective range), derived by Tirira and Bodart\(^{(25)}\) is presented in Table 1.

For \(^4\text{He}\) energy values below 3 MeV and \(\phi\) values below 30°, i.e. the most frequently used experimental conditions, several points with respect to the functional dependence of the non-Rutherford cross section \(\delta_{\text{NR}} = (d\sigma/d\Omega)^{\text{L}}\) should be noted:

- \(\delta_{\text{NR}}\) exhibits a minimum value for an energy \(E_{\text{min}}\) in the range 2.4–3 MeV for a recoil angle less than 30° (\(E_{\text{min}} = 2.41\text{ MeV at } 0°\)). As the angle increases from 0°, the cross-section minimum moves toward larger energy values.
- \(\delta_{\text{NR}}\) has its lowest value at \(\phi = 0°\) for \(E_{\text{He}} < E_{\text{min}}\).
- \(\delta_{\text{NR}}\) has its highest value at \(\phi = 0°\) for \(E_{\text{He}} > E_{\text{min}}\).
- \(\delta_{\text{NR}}\) appears to reach the same constant value around \(E_{\text{He}} = 3\text{ MeV for } 0 < \phi < 40°\).
- \(\delta_{\text{NR}}\) varies very slightly near 0° with respect to \(E_{\text{He}}\).
- \(\delta_{\text{NR}}\) varies slightly in the 0–30° range between 2 and 3 MeV.
- \(\delta_{\text{NR}}\) shows a quasi-Rutherford behavior for \(E_{\text{He}} < 1\text{ MeV}\).

Comparing previously published data sets and their own experimental results, Tirira and Bodart derived a simple analytical expression allowing the elastic recoil differential cross section in the laboratory to be calculated for any \(E_{\text{He}} - \phi\) couple, Equation (11)\(^{(25)}\):

\[
\ln \left(\frac{d\sigma}{d\Omega}\right)^{\text{L}} = A_1 E_{\text{He}} + A_2 + A_3 E_{\text{He}}^{-1} + A_4 E_{\text{He}}^{-2} \quad (11)
\]

Table 2 contains different data sets for \(A_i\) values, for \(0 \leq \phi \leq 40°\) and \(1 \leq E_{\text{He}} \leq 4\text{ MeV}\).

Other binary collisions such as \(^4\text{He}/^2\text{H}, ^4\text{He}/^3\text{H},\) and \(^3\text{He}/^3\text{H}\) have been treated in the same way.\(^{(126–30)}\) A detailed discussion on this subject and the corresponding analytical expressions are given by Tirira et al.\(^{(8)}\)

### 2.3 Energy–Depth Relationships

An incident ion with energy \(E_0\) impinges on a target surface with an angle of incidence \(\alpha\) with respect to the normal to the surface. Let us consider an elastic collision occurring at depth \(x\) beneath the target surface, the scattering direction makes an angle \(\phi\) with the incident direction and the recoil angle is \(\phi\). The path of the incoming ion before collision is simply expressed by Equation (12):

\[
L_{\text{in}} = \frac{x}{\cos \alpha} \quad (12)
\]

Its outgoing path is given by Equation (13):

\[
L_{\text{out}} = \frac{x}{\cos \alpha} \quad (13)
\]

where the outgoing angle has been chosen to be equal to the incoming one. The path of the recoiled target atom is then given by Equation (14):

\[
L_t = \frac{x}{\cos \beta} \quad (14)
\]

where \(\beta = \pi - \phi - \alpha\).

The energy of the incident ion just before the collision is given by Equation (15):

\[
E_0(x) = E_0 - \int_0^x \frac{1}{\cos \alpha} S(E) \, dl \quad (15)
\]

where \(dl\) is the differential path. The energy of the scattered incident ion leaving the target is given by Equation (16):

\[
E_1(x) = KE_0(x) - \int_0^x \frac{1}{\cos \alpha} S(E) \, dl \quad (16)
\]

and the energy of the recoiled target atom is given by Equation (17):

\[
E_2(x) = K'E_0(x) - \int_0^x \frac{1}{\cos \beta} S'_c(E) \, dl \quad (17)
\]

ELASTIC RECOIL DETECTION ANALYSIS

where \( S(E) \) and \( S_r(E) \) are the stopping powers for the incident ion and the recoiled target atom, respectively, in the target material considered.

2.4 Recoil Yield

For a thin target, the number of recoiled target atoms emitted in the depth range \( x - x + dx \) through an angle \( \phi \) in the solid angle \( \Delta \Omega \) is given by Equation (18):

\[
dN(x) = \frac{N_0 Q d\sigma(E, \phi)}{d\Omega \Delta \Omega} \tag{18}
\]

where \( N_0 \) is the target atomic density and \( Q \) the total number of incident ions. The total recoil yield is then obtained by integrating Equation (18) on the thickness \( t \) of the target sample, considering the differential cross section as constant along \( t \).

For a thick target, the analytical expression giving the recoil yield is slightly more complex because it has to take into account the variation of the differential cross sections with energy and all the energy spreading effects induced by particles traveling in matter.

2.5 Depth Resolution

Depth resolution \( \delta R_x \) strongly depends on total energy resolution of the system \( \delta E_T \). This factor includes:

- the detector energy resolution \( \delta E_d \);
- the fluctuations in projectile energy \( \delta E_p \);
- the energy spreading due to angular deviations \( \delta E_\theta \);
- the geometrical energy spreading \( \delta E_g \);
- the energy straggling during incoming and outgoing paths \( \delta E_s \);
- the multiple scattering contribution \( \delta E_{ms} \);
- the contribution from Doppler effect \( \delta E_D \);
- the energy spreading due to the absorber \( \delta E_a \); and
- the energy spreading due to surface roughness \( \delta E_{rou} \).

A detailed description of the methods used for evaluating each contribution has been given by Tirira et al.\(^{[8]}\)

3 CONVENTIONAL ELASTIC RECOIL SPECTROMETRY

3.1 Glancing (Reflection) Geometry

Figure 2 summarizes the experimental configuration called glancing or reflection geometry.

Several points should be noted:

- The beam spot size is enhanced by a factor \( (1/\cos \alpha) \) with respect to normal incidence owing to the oblique incidence \( \alpha \).

![Figure 2](image-url) Schematic view of glancing geometry.

- The surface barrier detector is preceded by an absorber foil dedicated to stopping the ions scattered in the direction \( \phi \).
- The analyzable depth is rather limited owing to the glancing geometry. The range from the surface is obtained by multiplying the true incident ion range in the target by a factor \( (\cos \alpha) \).
- This experimental configuration is absolutely prohibited with rough surface targets.

3.2 Transmission Geometry

Figure 3 summarizes the experimental configuration called transmission geometry.

Transmission geometry was the first experimental configuration used for ERDA measurements.\(^{[1, 31–33]}\) Several points should be noted:

- The thickness of the target and the incident energy of the \(^4\)He beam are strongly dependent, typically 20–25 \( \mu \)m for 3–3.5MeV.\(^{[34]}\)
- The presence of an absorber foil in front of the surface barrier detector is not necessary because the target itself slows down the scattered ions while they travel along their path until they are stopped.
- Practically, the surface barrier detector has to be placed as close as possible to the \( 0^\circ \) direction, but not directly in view of the incident beam direction to avoid severe irreversible damage in the case of target breaking.
- The analyzable depth is only limited by the range of recoiling protons; it can reach up to 6–7 \( \mu \)m for polymer or silica-based materials.\(^{[34, 35]}\)

![Figure 3](image-url) Schematic view of transmission geometry.

Table 3 permits comparison of the analytical performances offered by the two available geometries for hydrogen measurement.

Figure 4 gives two different examples of ERDA spectra obtained in glancing geometry for a hydrogenated NiC/Ti multilayer and a thick hydrogenated amorphous carbon layer in reflection geometry.

3.3 Data Processing

Conventional ERDA data are treated in the same way as RBS, using a reconstitution-comparison-iteration computer program. The first step in the process is to define the experimental configuration (incident energy, geometry, detector characteristics, and target description). Then a simulated spectrum is built using the collision kinematic equation, the energy-loss formalism, the elastic recoil cross-section table, and straggling and multiple scattering subroutines. Finally, the simulated spectrum is compared to the experimental data and adjusted in terms of elemental distributions, using a classical least-squares method until it matches correctly.

Several authors have proposed specific computer codes dedicated to ERDA interpretation. Our purpose, in this section, is not to describe in detail any specific approach. The references listed above constitute excellent starting points to get to know classical IBA tools. An IAEA intercomparison of some of the most used computer codes was published recently.

In the case of heavy-ion elastic recoil detection analysis (HI-ERDA), another approach known as slab analysis is often used instead of simulation and comparison. In the energy spectrum, a channel corresponds to a certain depth slice. The depth is calculated using scattering kinematics and either experimental or, more often, semiempirical stopping powers. The yield at different depths is then normalized using stopping powers and scattering cross sections for a given incident ion and sample atoms. If all the sample elements can be analyzed, the final depth profiles can be normalized to unity to obtain the atomic ratios. All the effects degrading depth resolution that are mentioned above are still visible in the depth profiles after slab analysis.

3.4 Standard Matrices and Ion-beam-induced Damage

IBA techniques are considered to be quantitative even without the use of reference samples provided that the differential cross section of the interaction observed is accurately known in the energy range investigated and also provided the experimental geometry (target and detector) is fully described.

However, the quantitative determination of any elemental depth distribution in a complex target material generally requires the use of a reference sample. This standard (or model sample) is investigated either to simplify the calculation procedure or to assess the profile extraction method. Moreover, finding a good hydrogen reference sample remains a particular problem owing to its high mobility in solids even under standard temperature conditions. The use of reference samples is highly recommended for accurate results in the case of HI-ERDA also; even in the case of thin films when all the elements present can be detected and concentrations normalized to unity.

Polymers would represent the most practical type of hydrogen reference samples because of their large H
content, their variety of formulation, their thickness range (from 3 μm up to several hundred micrometers) and their well-known core composition homogeneity. Nevertheless, there are two severe limitations:

- the thickness heterogeneity of thin films having thickness less than 20 μm and
- the sensitivity of polymer structure to ion beam bombardment.

Elemental losses are impossible to prevent and in practise polymers have to be replaced by hydrogen-implanted monocrystals (Si or Ge, for example). The versatility of implantation conditions (energy and fluence) is of major interest but conservation of the hydrogen profile for long periods of time is not guaranteed. The hydrogen mobility in silicon at 25°C is far from negligible. Metal hydrides such as TiH₂ or Ti₅D₃ (with x = 1 and y ~ 1.8) could be an alternative to implanted crystalline layers, but control of the stoichiometry is rather difficult. Hydrogenated amorphous carbon or silicon-carbide layers appear now to be a better compromise than hydride layers.

The choice of a multielemental reference sample requires a complete description of the investigated sample. Routine methods such as electron microprobe analysis (see Scanning Electron Microscopy in Analysis of Surfaces) must be very efficient to ensure the lateral composition homogeneity of the target material. The most important criterion is to choose a reference material with a similar composition in order to be able to neglect corrections for stopping power. Ceramics, glasses, or thin layers are the most useful materials for IBA standards provided that their sensitivity to ion bombardment has been checked before use.

Several effects can be inferred by an incident ion beam impinging on a radiation-sensitive material: electron excitation, ionization, atomic displacement, bond breaking, formation of charge defect centers, temperature increase, growth of an electrical gradient, and surface sputtering. The main consequences of these phenomena is the modification of the target composition and particularly the loss of certain elements of interest such as hydrogen, alkali metals, or halogen elements. An extensive review of beam damage is presented by Tirira et al.

A comprehensive bibliography is given and concrete examples discussed.

3.5 Microbeam-induced Elastic Recoil Detection Analysis

Microbeam-induced elastic recoil detection analysis (μERDA) is the only routinely available technique for hydrogen determination using a nuclear microprobe. Experiments in transmission geometry are, in general, easier to carry out than experiments in reflection geometry.

Transmission geometry is used in polymer science applications or in geological applications and reflection geometry is chosen for thin-layer characterization.

Figure 5 gives an example of an ERDA spectrum obtained in transmission geometry on a thin polyimide film (25 μm) preirradiated with 50-MeV 32S ions and measured with a 3.05-MeV 4He⁺ microbeam (5 × 5 μm², 200 pA). The heavy-ion irradiation induces the formation of hydrogen bubbles in the core of the modified polymer structure. Two of these hydrogen-rich zones are found in the spectrum between 3 and 5 μm from the surface.

4 VARIANT RECOIL METHODS

The energy discrimination between a scattered incident ion and a recoiled target atom is one of the major problems to be solved in ERDA. It can be based on the difference of energy loss in a given thickness of a well-known material. When m > M (4He²H collision), the scattered 4He loses a higher fraction of its energy than the recoil 1H reaching the detector. The use of an absorber foil (polymer or Al) in front of the detector allows discrimination by stopping the scattered events. This simple technique is currently the most adopted one for ERDA measurement (see Section 3) in transmission geometry, in which the target itself plays the role of the absorber foil. When m < M, this system is completely inefficient.

4.1 ΔE–E Telescope

The second way to solve the scattered/recoiled event ambiguity is to replace the absorber foil by a thin detector (10–20 μm). The device constituted by a couple of detectors is called a solid-state ΔE–E telescope.
Scattered ions are stopped in the $\Delta E$ detector and recoil events are detected in the $E$ detector ($\geq 100 \mu m$). Figure 6 is a scheme of such a detection device.

The solid $\Delta E$ detector can be replaced by a gas-ionization chamber. Telescopes have been used for ERDA measurements with $^4$He beams as well as with heavy-ion beams.

The mass and charge separation ability of a telescope are simply described by Equations (19) and (20):

$$\frac{\Delta M}{M} = \left[ \left( \frac{\Delta E_R}{E_R} \right)^2 + \left( \frac{\Delta dE}{dE} \right)^2 + \left( \frac{\Delta dx}{dx} \right)^2 \right]^{1/2}$$  \hspace{1cm} (19)

$$\frac{\Delta Z}{Z} = \frac{1}{2} \left[ \left( \frac{\Delta E_R}{E_R} \right)^2 + \left( \frac{\Delta dE}{dE} \right)^2 + \left( \frac{\Delta dx}{dx} \right)^2 \right]^{1/2}$$  \hspace{1cm} (20)

where $dE$ is the energy loss in the thin detector and $dx$ is the thickness of the thin detector.

The presence of an absorber foil in front of the detector in conventional ERDA induces a high straggling contribution because the recoil energy can be simply deduced by summing the energy loss in the thin detector $\Delta E$ and the residual energy $E_R$. Only the straggling contribution from the detector dead layers cannot be suppressed. For example, a depth resolution better than 25 nm has been obtained for oxygen determination in native oxide layers using a 43-MeV $^{65}$Cu beam. Siegele et al. have obtained a depth resolution better than 20 nm on stainless steel with 130-MeV $^{127}$I ions. A value of 10 nm has been obtained by Assman.

Figure 7 illustrates the increased selectivity offered by the use of a solid-state telescope for simultaneous detection of $^1$H, $^2$H, and $^3$H with 4-MeV $^4$He$^+$ in a titanium hydride layer.

### 4.2 Time-of-flight Elastic Recoil Detection Analysis

The determination of mass separation between scattered and recoil ions by measuring the difference in their time of flight (TOF) for a given path length was first introduced in the mid-1980s. The principle of TOF spectrometry is based on the measurement of particle flight time between a start gate and a stop gate giving two distinct signals. Simultaneously, the total energy of the particles is measured by means of a solid-state or gas-ionization detector. Figure 8 schematically describes a TOF spectrometer.

The flight time $t_f = t_2 - t_1$ of a particle with mass $M$ and energy $E_R$ traveling along a path of length $L$ is given by Equation (21):

$$t_f = t_2 - t_1 = L \left( \frac{M}{2E_R} \right)^{1/2}$$  \hspace{1cm} (21)

If the TOF spectrometer is set up with an entrance window of thickness $x$, Equation (20) becomes Equation (22):

$$t_f = L \left[ \frac{M}{2[E_R - S(E)x]} \right]^{1/2}$$  \hspace{1cm} (22)

where $S(E)$ is the stopping power of the window material for recoil ion $M$ at energy $E_R$.

The time detector is generally an electrostatic mirror protected by a thin carbon foil (0.5–20 $\mu g \text{cm}^{-2}$) so that the energy recorded by the surface barrier detector, which is also often used as the stop-signal detector, is given by Equation (23):

$$E = E_R - S(E)x$$  \hspace{1cm} (23)
where \( x \) is the thickness of one or, in the case of two timing gates, two carbon foils. The carbon foil of the first electrostatic mirror serves as the entrance window for the TOF spectrometer. Typical flight time values are in the range 30–100 ns for a flight path of about 50 cm. Normally, the energy spectra used in the analysis is converted from timing signal. The two main reasons for this are (i) the normally better resolution for other elements than for H and He and (ii) the linear calibration for all the elements, which is not the case for a solid-state detector. A well-known limitation of the TOF-E technique is the poor detection efficiency (typically 10–60\%) of timing gates for H, which is strongly stopping force and therefore, energy dependent. An elegant way to get around this limitation is to use the fact that for elements heavier than B, the detection efficiency is very close to 100\%, and if the timing window is long enough, almost all noncoincident events seen only by the E detector are hydrogen. By summing up coincident events from the H curve and noncoincident events, 100\% detection efficiency is obtained for H. This technique is described in detail in two round-robin characterizations where H was also studied.\(^{59,60}\)

Figure 9 gives an example of the application of a TOF spectrometer for the ERDA characterization of a glass ceramic with an 84-MeV \( ^{127} \text{I} \) beam.\(^8\) It can be seen that the mass resolution is less than 1 for low masses, and that \(^{10}\text{B} \) and \(^{11}\text{B} \) isotopes are clearly distinguishable. Nevertheless, mass resolution decreases with increasing mass so that \(^{27}\text{Al} \) and \(^{28}\text{Si} \) cannot be separated. This is mostly due to poor energy resolution of the solid-state detector. The mass resolution can be drastically improved by introducing a gas-ionization detector equipped with a thin SiN entrance window.\(^{61}\) However, Al and Si can be readily separated with a \( \Delta E - E \) gas detector as shown by Siegele et al.\(^{54}\)

A characteristic feature for TOF-ERDA is the fact that depth resolution at the surface improves when the energy of incident ion is lowered. This is due to the fact that the elemental energy spectra used in the analysis are converted from TOF spectra. Even with a simple TOF-E telescope, all elements below Ne can be separated from each other with projectile (Cl, Br, and I) energies below 20 MeV.

### 4.3 Coincidence Spectrometry

In the first ERDA experiments, from Cohen in 1972\(^{31}\) to L’Ecuyer in 1976,\(^1\) transmission geometry together with coincident detection of scattered and recoil particles were applied to achieve mass selectivity, to reduce the background, and to improve the sensitivity.

By detecting both particles, four parameters can easily be obtained: \( E_S, E_R, \theta, \) and \( \phi \). Thus the mass of the recoil nucleus \( M \) and the interaction depth \( x \) can be deduced according to Figure 10. One variation of this technique, proton-proton scattering utilized by Reichart et al., allows sensitive 3D profiling of hydrogen down to ppm-levels.\(^{62}\)

Two families of ERDA coincidence methods can be distinguished: those carefully adjusting \( \theta \) and \( \phi \) to achieve mass selectivity and to reduce the background, and those carefully measuring \( E_S \) and \( E_R \) to eliminate \( \theta \) and \( \phi \).

Depth information is the ultimate goal of the first family of methods; this can be deduced from energy measurement. Large solid detectors are generally used in the second family of methods, and as a result, depth resolution is sacrificed. Figures 11 and 12 give one example of the application of each method.

Partial separation of \(^{63}\text{Cu} \) and \(^{65}\text{Cu} \) has been obtained by Klein et al.\(^{63}\) using a pair of position-sensitive detectors at the GSI heavy-ion microprobe (Darmstadt,
Germany) on a sandwich target (LiF/Cu/LiF/Cu/LiF) with 1.4-MeV amu\(^{-1}\) \(^{58}\)Ni ions. The dominant peak in Figure 12(a) corresponds to recoiled carbon atoms; recoiled oxygen is seen in the spectrum at higher He energies. Figure 12(b) is similar to Figure 12(a), but rotated by 180°, the surface line corresponds to the scattering process at the rear surface of the target.

### 4.4 Electromagnetic Cross Filters (\(E \times B\))

The Canadian group from Varennes was the first to propose the use of an electromagnetic cross filter as an achromatic mass and charge selector and not only as a Wien filter.\(^{65,66}\) A typical \(E \times B\) (electric and magnetic crossed fields) device for ERDA measurement is shown in Figure 13.

When a particle passes through the \(E \times B\) filter, Equations (24) and (25) describe its exact movement:

\[
\frac{m}{\tau} \frac{dv_y}{d\tau} = q(E - v_x B) \tag{24}
\]

\[
\frac{m}{\tau} \frac{dv_x}{d\tau} = qv_y B \tag{25}
\]

Assuming \(v_x = v_0\) and \(v_y = 0\), they reduce to Equation (26):

\[
\frac{m}{\tau} \frac{dv_x}{d\tau} = q(E - v_0 B) \tag{26}
\]

At the exit of the filter, the particle is deviated by an angle \(\alpha\) given by Equation (27):

\[
\sin \alpha \approx \alpha = \frac{qL(E - v_0 B)}{mv_0^2} \tag{27}
\]

where \(L\) is the total length of the \(E \times B\) filter.

The filter should deflect particles of all energies by the same angle; this condition is satisfied when Equation (28) applies:

\[
\frac{d\alpha}{dE} = 0 \quad \text{or} \quad E = \frac{Bv_0}{2} \tag{28}
\]
Typical values for \( L \), \( B \), and \( E \) are, respectively, 70–80 mm, 1 kG, and 1.5–2 kV cm\(^{-1}\).

Electromagnetic cross filters have been evolving since 1995 and more sophisticated devices have appeared such as the \( B - E \times B - B \) filter proposed by Serruys, which has been described previously\(^{(8)}\).

The Canadian group from INRS Varennes and A. Chevarier’s group in France (Lyon University) have collaborated together on the use of the \( E \times B \) filter to characterize amorphous hydrogenated layers. They have shown that hydrogen desorption induced by 2.5-MeV \(^4\)He\(^+\) with or without previous deuterium implantation was smaller for a-SiC:H than for a-C:H layers\(^{(11)}\). Figure 14 compares the hydrogen distributions in a-SiC:H and a-C:H layers after a deuterium implantation at a level between 2.2 and 3.5 \( \times 10^{16} \) D cm\(^{-2}\).

5 HIGH-ENERGY AND HEAVY-ION ELASTIC RECOIL SPECTROMETRY

As discussed in Section 2, low-energy \(^4\)He (2–4 MeV)-induced ERDA is adapted to profile target nuclei lighter than the projectile; generally \(^1\)H and \(^2\)H. Using a specific coincidence detection device allows the researcher to extend the profiled mass range to target nuclei heavier than the projectile (see Section 3). There are two other means to improve the range of analyzable elements and the total explored depth. The first consists in increasing the energy of the incident \(^4\)He beam to improve the energy separation between the contributions of the different target components and also to take advantage of the increase in the non-Rutherford cross section for light elements\(^{(67,68)}\). The second consists in increasing both the mass and the energy of the incident ion beam; this technique is called high-energy HI-ERDA\(^{(48,69–71)}\). The selectivity is thus largely improved; this was the configuration adopted by L’Ecuyer et al. in 1976 to investigate multilayered structures\(^{(1)}\).

5.1 High-energy \(^4\)He-induced Elastic Recoil

When \(^4\)He incident energy increases above 1 MeV, Rutherford scattering is no longer an applicable model. High-energy \(^4\)He scattering in light elements has a non-Rutherford behavior and cross-section resonances exist for several couples \(^4\)He/target nucleus, as shown in Figure 15 for carbon and oxygen.

Figure 16 shows the ERDA spectrum for \(^{12}\)C recoil of an Al/C sandwich target, obtained using a 30 MeV \( \alpha \)-particle beam in transmission geometry.

5.2 High-energy Heavy-ion-induced Elastic Recoil

Equation (4), describing the kinematics of the collision \( m/M \), with \( m \gg M \) becomes Equation (29):

\[
E' = 4E_0 \cos^2 \phi \frac{M}{m}
\]  

(29)

The interaction cross section follows Rutherford behavior as long as the incident energy is below the threshold energy defined by Equation (9).

The analytical expression of the differential recoil cross section given by Equation (8) becomes Equation (30):

\[
\frac{d\sigma}{d\Omega} = \left( \frac{Ze^2}{2E_0} \right)^2 \left[ (m/M)^2 \cos^3 \phi \right]
\]  

(30)

Several points should be noted:

- The differential cross section is nearly independent of the recoil mass because the \((Z/M)\) ratio ranges...
between 0.4 and 0.5 for all the elements except hydrogen.

- For hydrogen recoils \((Z/M) = 1\) and the differential cross section is increased by a factor of four relative to the other recoiled target atoms.

- The sensitivity of high-energy HI-ERDA increases strongly with increasing \(Z\). Anyhow, if a sophisticated detection system like \(\Delta E - E\) or TOF-E is used in the analysis, the high-\(Z\) projectile does not necessarily provide the lowest detection limit, but that can be obtained with lighter projectiles giving more energy and therefore better separation in the 2-D histogram for the recoils.

- The selectivity of high-energy HI-ERDA decreases with increasing \(Z\). For example, C, N, and O can be separated well in stainless steel using a 136-MeV \(^{127}\)I beam,\(^73\) but transition elements such as Cr, Fe, and Ni cannot be properly separated using 136-MeV \(^{127}\)I and the Bragg counter as shown in Figure 17. Nevertheless, Siegele et al. have shown that this separation is possible at 136 MeV, using a telescope with a gas chamber as the \(\Delta E\) detector.\(^76\)

- The differential cross section increases with increasing recoil angle \(\phi\) (factor 5 between 30 and 60°), but simultaneously the recoil energy is reduced. Generally, the detector system is located around 40°.

High-energy HI-ERDA requires specific detection devices such as those described in Section 4 (TOF
spectrometer or telescope). Electrostatic or magnetic spectrometers and ionization chambers are also in use.\(^{(68)}\) Data processing is generally based on two or more parameter data acquisition and the elemental information is expressed in matrix form.

The analytical performance offered by high-energy HI-ERDA, particularly depth resolution, depends strongly on the total energy resolution of the detection system, on the nature and energy of incident ions and recoil particles, and on the depth where the collision has occurred. Dollinger et al. have reported a surface depth resolution of 8 nm for hydrogen determination in a thin carbon film bombarded by 120-MeV \(^{197}\)Au ions in transmission geometry using a large magnetic spectrograph.\(^{(69)}\) For carbon/boron multilayers deposited on a thick silicon substrate, a surface depth resolution of less than 1 nm is achieved in reflection geometry using the same beam parameters.\(^{(69)}\) With low-energy ions and standard TOF-E telescope Brijs et al. demonstrated a depth resolution of 2 nm at the surface for H, N, and Si when characterizing very thin SiO\(_2\)/Si\(_3\)N\(_4\)/SiO\(_2\) film stacks using glancing angles.\(^{(77)}\) Measurement using 6-MeV \(^{35}\)Cl incident ions and very glancing \(3 + 35 = 38\) angle in reflection geometry is presented in Figure 18.

Normal ERDA geometry with the detector around \(40^\circ\) also offers good possibilities for the use of forward scattered incident ions, in addition to recoils, in the analysis. One possibility is to use light incident ion and do forward scattering analysis. The benefit of this is the high cross section and good depth resolution because of the small energy spread due to multiple scattering and kinematics. An example of this is the study of 6-nm HfSiO and 25-nm NiSi films on silicon using 3–8-MeV \(^{16}\)O ions as projectiles.\(^{(78)}\) The use of scattered incident ions with recoiled target atoms in the analysis is demonstrated in Figure 19 where an atomic layer deposited Li–La–O film was measured using a 16-MeV \(^{60}\)Cu beam. The recoiled La atoms suffered greatly from multiple scattering and could not be used in the analysis without proper MC simulations, but as La is the only heavy element present, scattered \(^{60}\)Cu could be used instead. As two different scattering cross sections were used, the scattering angle had to be known very accurately.
The main limitation on analytical performance in high-energy HI-ERDA (depth resolution, sensitivity, or analyzed depth) is attributed to the behavior of the target material under ion bombardment. In the case of films with a thickness of the order of nanometers, the sputtering phenomenon, which is directly proportional to the nuclear energy loss, has to be taken into account when analyzing the measurements. In the case of thicker films, especially of polymers, a much more visible effect is the loss of light elements throughout the film thickness. In the case of porous low-\textit{k} materials, the losses were found to be directly proportional to the energy loss of incident ions in the films and therefore to minimize the losses, the heaviest possible ion had to be used in the analysis.\(^{79}\)

Figures 20 and 21 give two different examples of the use of high-energy HI-ERDA. The first example deals with the analysis of an 80-nm silicon oxynitride film coated on 30-nm SiO\textsubscript{2} deposited on Si with 30-MeV \textsuperscript{28}Si ions.\(^{80}\) (Reproduced with the kind permission of Elsevier Science and Plenum Press.)

Another general feature of HI-ERDA that has a great effect on the analysis reliability is multiple scattering, which, for more detailed analysis, can be divided to multiple and plural scattering. This multiple scattering causes angular spread, which can be described with analytical functions.\(^{82-84,85}\) Equally important in the analysis are events where the scattering occurs closer to the sample atom nucleus resulting in a large angle...
scattering. Although these events are scarce, they can play an important role in the analysis. These scatterings are referred as plural scattering. Due to the nature of these events, no analytical function has been used to simulate them and they require full MC simulations. Multiple and plural scattering effects are strongly enhanced if the studied sample contains heavy elements; to carry out a very detailed analysis, the MC-simulation program should be used. The most sophisticated one at the moment is MCERD by Kai Arstila, which can, due to several computational enhancements, do full simulations in roughly the same time as it takes to measure the sample. In Figure 22 an example of the use of MCERD in the analysis is shown for the same measurement as in Figure 18. The experimental energy spectra are well reproduced; the low-energy tails, and reliable depth profiles are also obtained. The conclusion of rising Si content deeper in the film drawn on the basis of slab analysis (Figure 18) can be proven to be wrong by MC-based analysis. In addition to MC simulations, also Molecular Dynamics simulations have a great potential in interpreting IBA results.

6 APPLICATION EXAMPLES OF ELASTIC RECOIL DETECTION ANALYSIS FOR PROFILING HYDROGEN AND OTHER ELEMENTS

Four main application fields can be essentially distinguished for ERDA measurement, using either a low-energy $^4$He beam, higher energy $^4$He, or heavier ions: polymer science, microelectronics, thin films, and interface reactions. Each of these fields is illustrated in this section.

6.1 Polymer Sciences

Polymers are the most hydrogenated media encountered among solids. Three complementary topics of interest have given rise to the development of ERDA-based studies: the investigation of polymer surface properties, the hydrogen distribution in polymer blends and the irradiation behavior of polymers.

Many application examples have been presented and discussed by Tirira et al. Only some of them are presented in this article.

For example, Chou et al. have studied the modifications induced by radio frequency or microwave treatment under a D$_2$O atmosphere of polyimide films. They showed that the polyimide surface exhibited a D uptake proportional to the time of treatment. Moreover, a correlation has appeared between the surface concentration of hydroxy groups and the development of surface morphology during plasma treatment.

Green et al. studied the segregation of deuterated copolymer (molecular weight $M$ in the range 87 000–520 000) at the interface of a homopolymer blend...
(polystyrene/poly(vinyl methyl ether) with a molecular weight between 100,000 and 200,000) using 2.8-MeV $^4$He ions. They have shown that the diffusion coefficient of deuterated polymer varies as $M^{-2}$.

Composto et al. measured the diffusion coefficient of polymer molecules (deuterated polystyrene and deuterated poly(xylenyl ether) chains) in a complex polymeric structure using D as a tracer. Diffusion coefficients have shown to be independent of the matrix molecular weight and to decrease as $M^{-2}$.

Several authors have applied ERDA to evaluate the degradation of polymer composition under charged-particle bombardment. Wang et al. have investigated the modification of the electrical conductivity of high-temperature and high-performance polyetheretherketone (PEEK) and polyethersulfone polymers by ion implantation (50 and 180 keV As and Xe ions). A two-component regime has been found in which dominance depends on the implantation fluence ($<10^{15}$ ions cm$^{-2}$ or $>10^{17}$ ions cm$^{-2}$). Another example of ERDA study of polymer degradation was given in Section 3. Figure 5 corresponds to the application of µERDA for polymer characterization after high-energy heavy-ion bombardment. In this case, 50-MeV $^{32}$S ions were previously used to irradiate thin polyimide foils (25 µm). Bombardment-induced bond breaking leads to the formation of hydrogen-rich zones (micrometric bubbles or association of nanometric bubbles) trapped in the degraded polymer structure, as seen in Figure 5.

6.2 Semiconductor Materials

In this area, ERDA measurements are generally dedicated to profiling successive thin layers coated on a crystalline semiconductor substrate (Si, Ge, or GaAs) having different compositions and thicknesses.

The hydrogen profile is measured using a conventional approach with $^4$He ions as shown by Wang et al. or Barbour et al. Other light elements such as C, N, and O have been profiled using high-energy HI-ERDA.

Wang et al. have profiled hydrogen in semi-insulating polysilicon films. Figures 23 and 24 show the hydrogen recoil spectra obtained on films immersed in a gas flow reactant mixture ($N_2O/SiH_4$) in various ratios or annealed between 700 and 1000 °C for 30 min for a given gas reactant ratio. The film deposition rate decreases when the $N_2O/SiH_4$ ratio increases owing to the increase in oxygen concentration. The H content of the film decreases when the annealing temperature increases owing to the densification and restructuring of the film. Barbour et al. have shown that for silicon nitride film deposition by electron cyclotron resonance, the hydrogen content of the film was minimized when the stoichiometry was closest to $Si_3N_x$.

![Figure 23](image-url) Hydrogen recoil spectra for polysilicon samples immersed in a $N_2O/SiH_4$ flow with various $N_2O/SiH_4$ ratios. (Data reproduced from Wang et al., with the kind permission of Elsevier Science and Plenum Press.)
6.3 Thin Films

In the case of thin-film monolayered or multilayered structures, ion beam methods have been revealed to be powerful characterization tools, particularly considering the HI-ERDA\(^\text{94}\) and coupling of RBS with ERDA.\(^\text{95–97}\)

The development of materials based on hydrogenated amorphous carbon “diamond-like” or silicon-carbide layers, because of their promising tribological properties, strongly influenced the interest in ERDA in the early 1990s.\(^\text{98–101}\)

The relationship between the optical and electrical properties of hydrogenated amorphous silicon carbon films and their stoichiometry have been determined combining RBS and \(^{4}\)He-induced ERDA by Compagnini et al.\(^\text{95}\) A hydrogen concentration of 30 atom\% was shown to increase the optical energy gap by a factor of two and the electrical resistivity by several orders of magnitude.

Figure 25 gives three recoil spectra obtained on a:C–H or a:C–D layers. Hydrogen implantation in the a:C–D layer was shown to induce a large surface D release,\(^\text{99}\) extending to at least 80% of the analyzed depth (0–0.3 \(\mu\)m). Microelectronics is an important driving force in the development of this method. IBA has played an important role in the development of films replacing SiO\(_2\) as a gate oxide\(^\text{102}\) and the role of IBA in the film development has been very important. Another important thin-film application related to microelectronics has been Cu diffusion barriers like TiN\(^\text{103}\) and TaN.\(^\text{104,105}\) During the development process, deposited films normally contain substantial amounts of H, C, and O due to the precursors used – HI-ERDA can easily provide this information.

6.4 Interface Reactivity

This field of application corresponds to the experimental study of atomic transport mechanisms near a solid/solid or a solid/liquid interface, for example, oxide corrosion behavior.\(^\text{106,107}\) wear properties of treated metal, amorphous layers, or glass surfaces.\(^\text{108–113}\) Intensive use of ERDA has been reported by the Canadian group from Varennes\(^\text{114}\) and by the French group from the University of Lyon.\(^\text{11}\) These two groups have collaborated in studying some candidate materials for fusion reactor device coatings that act as facings for the plasma. Essentially, they studied hydrogen loss under irradiation and annealing conditions.

Figure 26 shows the erosion of the hydrogen depth profile in an a:C–H layer after \(^{4}\)He\(^+\) bombardment at
6.5 Other Application Examples

Other conventional ERDA or high-energy HI-ERDA applications have been reported since the late 1980s. For example, Mosbah et al. successfully proposed the use of ERDA in transmission geometry to measure the water content of melt inclusions trapped in minerals. Their first published data concerned inclusions from Pantelleria, San Pietro, and Guadeloupe: water contents ranged between 3.4 and 11.8 wt% and agreed well with theoretical calculations. Naitoh et al. have studied the reordering of an aluminum-adsorbed silicon surface like $\sqrt{3} \times \sqrt{3}$ Al/Si (111) induced by hydrogen sorption. They found that saturation occurs for a hydrogen coverage of about $1.3 \times 10^{15}$ H cm$^{-2}$. One totally new application for the TOF-ERDA telescope was introduced by Zhang et al. in 2001. For doing stopping force measurements, they installed a movable thin film between the second timing gate and energy detector and could then obtain continuous stopping curves for this film. This idea has now been used in many places for stopping force measurements, and has given better stopping values for the IBA community.

7 CONCLUSION

Three of the most striking characteristics of the ERDA method are its wide usable energy range from 350 keV to 1 GeV, its strong versatility in terms of detection configurations and variants, and with HI-ERDA, the possibility of depth profiling all the sample elements from H to Bi in a single measurement.

Besides the fact that it remains a delicate method, ERDA has featured in IBA-related conferences as the most promising and evolving technique for quantitative determination of elemental depth profiles in solids, from hydrogen to medium and even high mass numbers. In this approach, no prior knowledge of the sample is required and good results can be obtained without standard samples. The basic physics of the elastic collision process has made substantial progress since the late 1980s, especially when considering differential cross-section measurements and models or data-processing methods. Moreover, the spectacular development of high-energy HI-ERDA since the beginning of the 1990s must be emphasized. It is based on the strong theoretical and experimental capabilities derived from nuclear physics research (experimental devices, technical procedures, and theoretical models) that have brought a constant source of improvement to ERDA users for materials science applications. More and more IBA laboratories worldwide have developed specific facilities for applying ERDA to various problems in this field. In addition to
high-energy HI-ERDA, special TOF-E telescopes have been constructed for laboratories with smaller (1.7–3-MV terminal voltage) tandem accelerators, making this unique analysis technique available to more users.

The different application examples presented and discussed in the above sections constitute a good sample of the use of ERDA.

ERDA is the most practical IBA technique available for profiling hydrogen isotopes in the near-surface region of solids from 100 nm to 10 µm with a depth resolution of 20 nm for conventional ERDA and even 1 nm for HI-ERDA at the surface. The use of resonant nuclear reactions induced by high-energy heavy-ion beams to profile hydrogen seems to be restricted to specific applications and particularly to samples able to support high fluxes of 0.4–0.5-MeV amu\(^{-1}\) \(^{15}\)N ions.\(^{118}\) A round-robin characterization of ultrathin to thin (1–100 nm) aluminum oxynitride (AINO) films was organized and the participants used different IBA techniques.\(^{60}\) This paper gives a good overview of the possibilities and limitations of present IBA techniques in the case of thin films. Considering the analytical capabilities of SIMS, it must be noted that besides its excellent depth resolution and its very strong sensitivity, SIMS is a destructive technique and the calibration of the erosion rate of the target under investigation remains difficult. Nevertheless, the technical improvements encountered with the SIMS machines of the last generation tended to enhance the competition between these two methods.

The future of ERDA looks bright. In three decades, it has matured from something new and exciting to a widely used and trusted technique. In the beginning, the technique was utilized in big laboratories mostly concentrating on nuclear physics, but having plenty of useful instruments around. In the next phase, smaller laboratories, which had mostly concentrated on RBS adopted the conventional ERDA technique, but the instrumentation development was still concentrated on bigger institutes that had mostly high-energy heavy beams available. This millennium, the development has again been toward smaller accelerators, but now using HI-ERDA usually with TOF-E detectors. In these laboratories, the use of 5–20-MeV heavy incident beams have replaced, in many applications, the previously intensively used RBS and nuclear reaction analysis (NRA). This development toward lower energies is likely to continue as large tandem accelerators are not constructed anymore and old ones are being dismantled.

It is not difficult to predict that, in the future, accurate ERD analysis will be performed by means of MC-based simulation software capable of handling properly both multiple and plural scattering, and also all the instrumental effects that broaden the energy spectra. With the aid of this type of analysis, the surface depth resolution, and especially the reliability of analysis deeper in the sample, will be pushed to a new level.

ACKNOWLEDGMENTS

Dr. Kai Arstila is acknowledged for the MC simulations.

# Elemental Analysis by Isotope Dilution

T.M. Bahrainwala and Z.R. Turel  
*The Institute of Science, Mumbai, India*

## 1 Introduction

The measurement of extremely small traces of materials, which cannot be determined by normal analytical techniques, becomes possible and even relatively rapid and simple if the element can be made radioactive by the action of neutrons or charged particles. Nuclear techniques possess exceptional advantages in having extraordinary sensitivity, selectivity in detection and determination, speed and simplicity.

One of the nuclear techniques applied in trace and ultratrace analysis is isotope dilution analysis (IDA) which was first introduced by Hevesy and Hobbie in 1932. The great advantage of the method lies in the fact that it can be used even when the procedure involves loss of material or does not allow a complete separation of the element or compound. The isotope dilution method has found several applications in the determination of geological ages, fission yields and other problems in nuclear physics and chemistry.

Various techniques involved in IDA such as substochiometry, liquid chromatography (LC) and radiometric titration are discussed along with the application of this technique to the estimation of elements in complex matrices as reported in the literature.

## References

The measurement of extremely small traces of materials, which cannot be determined by normal analytical techniques, becomes possible and even relatively rapid and simple if the element can be made radioactive by the action of neutrons or charged particles. Nuclear techniques possess exceptional advantages in having extraordinary sensitivity, selectivity in detection and determination, speed and simplicity.

Nuclear techniques possess exceptional advantages in having extraordinary sensitivity, selectivity in detection and determination, speed and simplicity. The certainty in identification is excellent as it involves half-life measurement, type of disintegration and energy measurement of the emitted radiation, which are unique properties of an isotope. The sensitivity in many cases is as high as $10^{-10}$ g and in special cases it attains $10^{-12}$ g.
Isotopes are elements (nuclides) having the same atomic number and different mass number. They are classified as stable isotopes (SIs) and radioisotopes (RIs). In IDA, a RI is used as the ‘marked’ analyte. It has the same behavior as the analyte and is called a ‘tracer’, ‘spike’ or ‘label’.

One of the nuclear techniques applied in trace and ultratrace analysis is IDA. In the isotope dilution method the isotopic composition of an element remains constant throughout a series of chemical reactions. A SI may be used instead of a radioactive isotope, in which case the concentration must be determined by mass spectrometry (MS) or by some other appropriate procedure. The great advantage of the method lies in the fact that it can be used even when the procedure involves loss of material or does not allow a complete separation of the element or compound. It is therefore particularly useful in the measurement of rare earths, fission products and complex mixtures of organic or biomedical compounds.

IDA and reverse isotope dilution analysis (RIDA) have found useful applications with SIs and radioactive isotopes. With the development of MS, and the availability of separated SIs and radioactive isotopes, the isotope dilution method has found several applications in the determination of geological ages, fission yields and in other problems in nuclear physics. Accuracies of a few percent may be obtained for some elements that are present in concentrations as low as parts per billion (ppb) or parts per trillion (ppt).

2 HISTORY

The term IDA was first introduced in 1940 by Rittenburg and Foster. Hevesy and Hobbie\(^1\) first introduced the method for determining traces of lead present in a mineral in about one part in 10\(^6\); lead was measured by adding Ra D and then depositing PbO\(_2\) anodically. Haissinsky\(^2\) used a similar technique for measuring potassium in the presence of other alkali metals. Similarly, \(^35\)S was used to analyze a mixture of benzyl derivatives of sulfides, sulfones and sulfoxides.\(^3\) Other measurements reported in the literature during the initial stages of the development of the method include naphthalene in coal tar,\(^4\) \(^\gamma\)-hexachlorobenzene,\(^5\) penicillin,\(^6\) vitamin B\(_{12}\) and other organic compounds. In the case of penicillin, the molecule was labelled with \(^13\)C.

A great advantage of IDA is that it does not require complete separation of the analyte from the sample. However, the quantity of the analyte separated from the matrix must be determined using an appropriate method, e.g. by gravimetry or spectrometry. This is a disadvantageous feature of the classical form of IDA.

To overcome this problem, substoichiometric isotope dilution analysis (Subst-IDA) was proposed in 1958 by Ruzicka and Stary\(^7\) where only the measurement of radioactivities is required. The procedure is rapid and easy, and effects of interfering substances are lowered.\(^8\)

In 1974, the ‘sub- and superequivalence (SSE) method’ was introduced into IDA.\(^9\) It does not need such a strict reliance on the stability constant as the Subst-IDA mentioned above. Various analytical techniques, such as solvent extraction, ion exchange and precipitation, have been employed for the separation.

3 THEORY

3.1 Principle of Isotope Dilution Analysis

The various types of IDA such as classical IDA, Subst-IDA and sub- and superequivalence isotope dilution analysis (SSEIDA) are explained below using mathematical equations. Their characteristics are also explained.

3.1.1 Classical Isotope Dilution Analysis

In this method, an unknown amount \(x\) of analyte in the sample is spiked with a RI \(A\) (\(A\) = radioactivity; weight is negligible compared with the analyte in the sample). The specific activity of this analyte is \(S_x = A/x\). To the sample, a known amount \(y\) of the analyte is added, so the specific activity of the mixture becomes \(S_{x+y} = A/(x+y)\). An appropriate amount of reagent which reacts with the analyte is added next, and the pure product is separated. To remove any impurity from the matrix, purification must be carried out repeatedly. After that, the weight \(m_{x+y}\) and the radioactivity \(A_{x+y}\) of the product are measured. As the specific activity before and after the separation does not change, we have Equation (1):

\[
\frac{A}{x+y} = \frac{a_{x+y}}{m_{x+y}}
\]

The unknown quantity \(x\) to be determined is calculated from Equation (2):

\[
x = \frac{Am_{x+y}}{a_{x+y} - y}
\]

When the sample contains other components having properties similar to the analyte, it is difficult to obtain complete (100%) recovery of the pure analyte. In such a case, a yield correction would be made in the conventional analysis. However, this correction is not needed in IDA because only the specific activity needs to be known, as shown in the above equations. Therefore, complete separation and recovery are not required and, as a result, repeated purification steps may be made.
to remove impurities. This is the major advantage of IDA. The weight $m_{x+y}$ of the pure separated analyte must be determined by an appropriate method; however, this operation is troublesome and time-consuming. This situation is improved by Subst-IDA.

3.1.2 Substoichiometric Isotope Dilution Analysis

In this method, two samples containing an unknown amount ($x$) of the analyte are spiked ($S = A/x$) as in classical IDA, and standard solutions containing known amounts ($y, 3y$) of the analyte are added to them. The specific activities of the diluted solutions become $S_{x+y} = A/(x+y)$ and $S_{x+3y} = A/(x+3y)$. To each, substoichiometric amounts ($M$) of the reagent are added, then the products are separated from unreacted species. Assuming that the quantities ($m_{x+y}, m_{x+3y}$) separated from each sample are the same, namely $m_{x+y} = m_{x+3y} = m$, as the reagent used reacted quantitatively with the reactants, and the radioactivities obtained as $a_{x+y}, a_{x+3y}$, Equations (3) and (4) hold good as the specific activity does not change before and after the separation:

$$\frac{A}{x+y} = \frac{a_{x+y}}{m} \quad (3)$$

$$\frac{A}{x+3y} = \frac{a_{x+3y}}{m} \quad (4)$$

From these equations, we obtain Equation (5):

$$x = \frac{y(3a_{x+3y} - a_{x+y})}{a_{x+y} - a_{x+3y}} \quad (5)$$

Equation (5) shows that $x$ is obtained from the radioactivity without measurement of the weight $m$. This is a major advantage of Subst-IDA. Another point is that the amount of reagent used is substoichiometric compared with the quantity of the analyte and this leads to a decrease in consumption of the reagent by the interfering substances which react with reagent in the same way as the analyte, resulting in improvements in accuracy, precision and sensitivity.

The reagent must react with the analyte almost completely (nearly 100%) and be separated completely if the assumption $m_{x+y} = m_{x+2y}$ is to hold good. For this purpose, the stability constant of the product analyte and the reagent must be sufficiently large. Not many reagents satisfy this condition. This is a disadvantage of Subst-IDA, and to overcome this problem, SSEIDA was proposed.

3.1.3 Sub- and Superequivalence Isotope Dilution Analysis

The sample containing an unknown amount ($x$) of the spiked analyte ($A = \text{radioactivity}$, weight is negligible compared with $x$) is placed in each test tube in the first series. They are isotopically diluted by the addition of regularly increasing known amounts $iy$ ($i = 0, 1, 2, \ldots$) of the analyte so that their specific activities become $A/(x + iy)$. In the second series, $k$ times the unknown amount of the first series is placed in each test tube ($kA = \text{radioactivity}$, $kx = \text{amount of analyte}$); they are not isotopically diluted. All solutions in both series are brought to the same volume and same acidity by adding the appropriate amount of solvent. A definite amount of the reagents is added to each of them. The quantity of reagent is not always necessarily substoichiometric and is allowed to be larger (superequivalent) than that of the analyte. After the separation of the products (first series, $m_{x+iy}$; and second series, $m_{kx}$), their radioactivities are measured (first series, $a_{x+iy}$; second series, $a_{kx}$). As the specific activities do not change before and after the separation, we have Equations (6) and (7):

$$\frac{A}{x+iy} = \frac{a_{x+iy}}{m_{x+iy}} \quad (6)$$

$$\frac{kA}{kx} = \frac{a_{kx}}{m_{kx}} \quad (7)$$

for the first and second series, respectively. From these equations, we obtain Equation (8):

$$\frac{a_{kx}}{a_{x+iy}} = \left( \frac{m_{kx}}{m_{x+iy}} \right) \left( \frac{1}{x} \right) \left( \frac{iy + m_{kx}}{m_{x+iy}} \right) \quad (8)$$

The quantities $m_{x+iy}$ and $m_{kx}$ generally depend on the concentration of the analyte in the solution, namely $(x + iy)/V$ and $kx/V$. However, if one sample ($i$th increment) in the first series has the same concentration (isoconcentration point) of the analyte as that in the second series, the degree of reaction with the reagent and the degree of separation must be the same. This means that Equation (9) holds:

$$m_{x+iy} = m_{kx} \quad (9)$$

In this special case (at the isoconcentration point), Equation (10) is derived from Equations (6) and (7):  

$$\frac{a_{kx}}{a_{x+iy}} = k \quad (10)$$

Substituting Equations (9) and (10) into Equation (8), Equation (11) is obtained:

$$x = iy(k-1) \quad (11)$$

Thus, to determine $x$, it is necessary to find $j$. The value $j$ is virtual and does not necessarily have to be an integer (the value of $x$ is obtained by a graphical method). The number of samples of the second series is not necessarily
large, but several samples are generally used to obtain a reliable value by averaging.

As SSEIDA does not impose strict conditions on the reactivity and the quantity of the reagent, it has a wide range of choice of reagents compared with Subst-IDA. On the other hand, determination by classic IDA and Subst-IDA is possible using one or two samples (except for the multiple method), but more than four samples are necessary in SSEIDA to find the isoconcentration point. Therefore, this method demands more time and effort, and is not suitable for the analysis of small quantities of samples.

As is known from Equations (6) and (7), the effect of interfering substances is not negligible because their quantities in the matrix are different in the first and second series. Apart from this disadvantage, SSEIDA seems to be an excellent method when sensitive, precise and accurate determination by Subst-IDA is difficult.

### 3.1.4 Stable Isotope Dilution Analysis

The principle of stable IDA is almost the same as that of radioisotope dilution analysis (radio-IDA). The difference is that radio-IDA makes use of the change of specific activity but stable IDA must depend on the change in the isotope ratio. A mass spectrometer is the only instrument sensitive enough to measure the isotope ratio, so this method is also called isotope dilution mass spectrometry (IDMS).

Two isotopes (1 and 2) are selected from the various isotopes comprising the analyte to monitor the isotope ratio, so this method is also called isotope dilution mass spectrometry (IDMS). About 1 g, accurately weighed, of powdered salt sample was dissolved in 25 mL of doubly distilled water. Carrier solution (10–60 µg of iodide as NaI) and a suitable aliquot of 131I were added and the whole system was warmed to about 50 °C. After cooling, 5 mL of tartaric acid and 2 mL of potassium iodate solutions were added. This mixture acts as a mild oxidizing agent and oxidizes only I⁻ to I₂ and leaves chloride as such. Initially an attempt to use H₂SO₄ instead of tartaric acid was made, but this resulted in large-scale oxidation of chloride, causing interference in the substoichiometric stage. The iodine liberated was immediately extracted into CCl₄. To the organic phase 0.1 mL of AgNO₃ solution (in substoichiometric amount) and 10 mL water were added. Typically about 15 µg or its integral multiple amounts of Ag were added for substoichiometric extraction. This gave approximately 80% extraction. After thorough mixing, a colloidal solution of AgI was formed in the aqueous phase, to which, after separation, 1 mL of sodium thiocyanate solution was added. This resulted in the formation of NaI in the aqueous phase, which was then counted on a 1.75 × 2.00 in a well-type NaI(Tl) detector.

When analyzing actual samples of common salts, however, a standard solution of NaCl with a known concentration of iodine (as NaI) was simultaneously analyzed according to the standard procedure. Finally, the specific activities of the standard and the sample

### 3.2 Instruments Used

#### 3.2.1 Radioisotope Dilution Analysis

Some radio-IDA needs to use RIs, so instruments for measuring radioactivity are necessary. An appropriate instrument is selected depending on the kind and energy of radiation.

For example, a NaI(Tl) scintillation counter is commonly used to measure γ-rays from RIs such as 125I and a liquid scintillation counter is used for low-energy β-rays from 3H, 14C, etc. A Geiger–Müller counter is used for high-energy β-rays from 204Tl etc. A high-resolution HPGe semiconductor detector is able to measure γ-rays of various energies at the same time.

#### 3.2.2 Stable Isotope Dilution Analysis

Mass spectrometers are used in stable IDA to measure isotopic ratios. The instrument mainly consist of three parts, for ionization, separation of ions and detection. For ionization, glow discharge, inductively coupled plasma (ICP) and corona discharge are suitable for solid, liquid and gaseous samples. MS combined with gas chromatography (GC) and LC are useful for preliminary separation and concentration of the analyte.

An example of Subst-IDA for the determination of iodine in common salts using 131I as tracer is given below.

About 1 g, accurately weighed, of powdered salt sample was dissolved in 25 mL of doubly distilled water. Carrier solution (10–60 µg of iodide as NaI) and a suitable aliquot of 131I were added and the whole system was warmed to about 50 °C. After cooling, 5 mL of tartaric acid and 2 mL of potassium iodate solutions were added. This mixture acts as a mild oxidizing agent and oxidizes only I⁻ to I₂ and leaves chloride as such. Initially an attempt to use H₂SO₄ instead of tartaric acid was made, but this resulted in large-scale oxidation of chloride, causing interference in the substoichiometric stage. The iodine liberated was immediately extracted into CCl₄. To the organic phase 0.1 mL of AgNO₃ solution (in substoichiometric amount) and 10 mL water were added. Typically about 15 µg or its integral multiple amounts of Ag were added for substoichiometric extraction. This gave approximately 80% extraction. After thorough mixing, a colloidal solution of AgI was formed in the aqueous phase, to which, after separation, 1 mL of sodium thiocyanate solution was added. This resulted in the formation of NaI in the aqueous phase, which was then counted on a 1.75 × 2.00 in a well-type NaI(Tl) detector.

When analyzing actual samples of common salts, however, a standard solution of NaCl with a known concentration of iodine (as NaI) was simultaneously analyzed according to the standard procedure. Finally, the specific activities of the standard and the sample
 aliquots were compared and the concentration of iodine was calculated.

In order to ascertain the accuracy and precision of the method, several suitable mixtures of NaCl and NaI were analyzed. To a solution of nearly 1 g of NaCl, an aqueous solution containing 3–60 µg of NaI was added and its iodine content was determined.

Iodine is important as an essential trace element for humans, and its deficiency leads to goiter, a prominent disorder of the thyroid gland. The important sources of iodine are foodstuffs and beverages that contain seafoods and common salt. In order to circumvent the deficiency of iodine in many parts of the world, several countries have launched a program of dietary supplementation. Even such programs have not always been successful in countering goiter in some countries. In India, the consumption of seafood is very low and common salt is the only source of iodine. The Government of India has now launched a program for the consumption of iodized salts by the general public. Iodine has been determined by other methods also.

4 STATISTICAL EVALUATION OF THE METHOD WITH RESPECT TO ACCURACY, PRECISION AND SENSITIVITY OF ISOTOPE DILUTION ANALYSIS

4.1 Factors Affecting Precision

The precision of the weighing of the separated analyte is important. However, with Subst-IDA weighing is not required.

Errors in counting radioactivity also affect precision. The measurement should last long enough to lower the error $E$ to below 1% according to equation (14):

$$ T = \frac{10000}{E^2 r} $$

where $T$ = period of measurement and $r$ = counting rate.

4.2 Factors Affecting Accuracy

The tracer and carrier (diluent) must behave in the same manner as the analyte in the sample in order to obtain a constant specific activity throughout the procedure. For this purpose, properties such as valency state of the element and the kind of reagent must be made uniform at an early stage of analysis. Isotopic equilibrium between the tracer and the analyte must be complete.

Loss of analyte (in unknown amount) may be caused during dissolution by adsorption on the container wall, vaporization, etc. When an unknown amount of an analyte is lost before dilution with the tracer, it strongly affects the accuracy of the method. Therefore, it is desirable to mix the tracer and diluent with the sample in the earliest stages of the operation. Loss after exchange does not affect the accuracy.

In each analysis, a simple clean room is desirable to prevent contamination from the reagents, apparatus, atmosphere, etc. which affects the accuracy. It must be ensured that the radioactivity comes from only one type of nuclide, i.e. the sample is radiochemically pure. When there is another element which emits radiation similar to that of the tracer in the sample, it affects the accuracy. In these cases, the tracer should be purified.

4.3 Factors Affecting Sensitivity

The volume of the reaction mixture should be minimized to increase the sensitivity. The presence of interfering ions affects the sensitivity, but the effect is less in Subst-IDA and SSEIDA, so the sensitivity of these methods is higher than that of classical IDA.

5 LIMITATIONS OF THE METHOD

The use of the proposed method for the determination of amounts of metals larger than 1 mg is not advantageous, because physicochemical analytical methods may be used whose precision is, under these conditions, better than the precision of radiometric methods, which is controlled by the statistical character of the radioactive decay. The sensitivity of the method is limited by two factors: (a) the organic reagent employed cannot be diluted infinitely and (b) at present, RIs of sufficiently high specific activity are not at hand for all cases. The latter limitation has been solved to a certain extent by the development of procedures for the preparation of carrier-free RIs.

6 APPLICATION OF ISOTOPE DILUTION ANALYSIS TO THE DETERMINATION OF SOME REPRESENTATIVE ELEMENTS

6.1 Boron

A method has been described for determining traces of boron in silicon. The sample was dissolved in aqueous sodium hydroxide in the presence of $^{10}$B tracer, and boron was separated by modification of Morrison and Rupp's method of electrolysis through a cation-exchange membrane. Boron was finally determined by making isotope dilution measurements with a mass spectrometer with a thermal ionization source. The method has the advantage that quantitative separation of boron was not
necessary. Amounts of boron down to 0.001 µg can be determined to within ±30%.

6.2 Carbon
The sensitivity and precision of field-desorption MS are greatly improved by using an isotopically labelled standard compound and averaging the m/z values for a large number (e.g. 100 or 210) of spectral scans.\(^{(17)}\) Cationization involves the production of molecular ions with enhanced m/z values, e.g. when a mixture of glucose, \(^{13}\)C glucose and NaI was dissolved in water, and the solution was applied to a high-temperature field-desorption emitter, the spectrum contained peaks for the species \((M + Na)^+\). The use of such peaks, with correction for \(^{13}\)C glucose in the nominally unlabelled glucose, permits the determination of glucose with a mean error of ±7%. The method is considered to show promise for biomedical analysis.

Small amounts of carbon in metals have been determined by the isotope dilution method by using an omegatron.\(^{(18)}\) From 0.4 ppm to 6% of carbon in steel, iron, copper, tin, nickel, tungsten or molybdenum or in tungsten carbide was determined by heating the sample (in the form of a thin ribbon) at 1400 K in an atmosphere containing a known concentration of \(^{13}\)CO. After 3 h the concentration of \(^{13}\)CO and \(^{12}\)CO in this atmosphere were determined by MS using a dynamic mass spectrometer (omegatron). The coefficients of variation were <10%.

A method utilizing IDMS has been developed for the determination of carbon in sodium.\(^{(19)}\) The details of the method are described for the determination of elemental carbon employing Van Slyke oxidation, although, by choice of spike material, other forms of carbon may be determined. Accuracy and precision in the ranges of 50 ± 10 to 150 ± 25 µg of carbon have been demonstrated. The determination was not affected by the loss of generated carbon dioxide or by contamination from any source except carbon.

6.3 Nitrogen
The method described has been applied to the determination of nitrogen in Nb, W, Mo, La, Ce, Re, Fe, Cr and Ni.\(^{(20)}\) It is based on MS measurement of changes (effected by dilution with the nitrogen from the sample) in the isotopic composition of \(^{15}\)N used as an indicator. Nb was used as carrier for the indicator (forming nitrides) for improving the isotopic exchange between indicator and sample. The sensitivity was 1 ppm and the precision was 3% for 5 g samples containing 10 ppm of nitrogen.

6.4 Oxygen
Oxygen has been determined in iron and steel by a modified isotope dilution technique.\(^{(21)}\) Previous discrepancies in the determination of oxygen in steel by an isotope dilution and vacuum fusion technique were traced to adsorption of \(^{18}\)O on deposits in the furnace. By treating the specimen at dull-red heat with a measured volume of oxygen enriched in \(^{18}\)O and allowing it to cool before lowering it into the graphite crucible, good agreement was obtained between the two methods.

6.5 Phosphorus
In the method described, \(^{32}\)P-labeled sodium phosphate was used to determine 10–50 ppm of P in 3–5 g samples of triuranium octaoxide.\(^{(22)}\) The error was <3% and the reproducibility was satisfactory. The method depends on the precipitation of the P as molybdophosphate, which is converted into MgNH\(_4\)PO\(_4\) for counting.

The use of the isotope dilution technique to eliminate problems associated with demands for a high load capacity in column-coupling capillary isotachophoresis was studied.\(^{(23)}\) Determinations of phosphate present in a model mixture and in white wine served for the evaluation of this approach to quantitative analysis in isotachophoresis. A high selectivity of the analysis with acceptable accuracy and precision of the analysis of complex ionic mixtures in a short time are obvious advantages of this approach.

6.6 Sulfur
Adsorbed sulfate in soil was determined by adding a small quantity of carrier-free \(^{35}\)S as sulfate to a solution in equilibrium with the soil.\(^{(24)}\) The adsorbed sulfate was calculated using the isotopic dilution law from total added activity and the activity in the equilibrium solution. Total added activity and activity in the equilibrium fractions were determined by suspending soil in water overnight, adding a solution containing \(^{35}\)S, diluted to an activity close to 6.7 kBq, shaking the suspension for 2 h and centrifugation at 9000 rpm for 10 min. One part of the supernatant was used for liquid scintillation analysis and mixed with Quick Safe A. The remaining supernatant was filtered through a 0.2 µm membrane filter and sulfate was determined using a Dionex 2000i ion chromatograph equipped with an AS4 anion-exchange separation column. Phosphate-extractable sulfate was extracted with 10 mM calcium dihydrogenphosphate. Part of the supernatant was filtered through a 0.2 µm filter and analyzed by ion chromatography as before. The two methods gave corresponding results for fresh soil but for air-dried soil the extraction method yielded approximately 25% more adsorbed sulfate than the \(^{35}\)S method.

6.7 Argon
Radiogenic Ar was determined in rock samples by the method of isotope dilution with an AlCl\(_3\) standard
containing 38Ar. After exposure to a neutron flux, 1 g of AlCl₃ contained (4.48 ± 0.14) × 10⁻³ mL of 38Ar. Rock samples mixed with 0.5 g of irradiated AlCl₃ were placed in a silica tube attached to a vacuum system, and the isotope content of the released Ar was determined in a mass spectrometer. The 40Ar content of the rock sample was calculated with a correction for atmospheric Ar.

6.8 Potassium

Small amounts of K have been determined by IDA, involving an exhaustive chemical procedure. A method for the determination of K in minerals difficult to decompose by chemical means is described. Procedures for beryl and tourmaline are given. A method has also been described for the mass spectrometric determination of K in minerals containing <1% of K. The results agree reasonably well with those obtained by chemical methods.

6.9 Calcium

The IDMS determination of low concentrations of Ca in minerals has been discussed. The sample was decomposed with HF–HClO₄ after adding ⁴²Ca, then total Ca was separated from K and various other metals on a column of strongly acidic ion-exchange resin, complete removal of K being essential. The Ca content was calculated from the ratio of the peak intensity of ⁴⁰Ca to that of ⁴²Ca, as determined by MS. The dependence of the analytical error on the MS measurements is discussed. Calcium (0.15–0.004%) was determined in two feldspars and one lepidolite. The results (together with their precision) are reported.

An isotope dilution technique utilizing thermal ionization MS has been developed for the accurate determination of calcium in synthetic and serum samples at the 100 mg g⁻¹ level. Calcium was separated from a serum matrix by destruction of the organic matter with HClO₄ and HNO₃ followed by ion-exchange separation from interferences using AG50W-X8 100–200-mesh resin. An MS isotopic analysis procedure was developed using a Ca(NO₃)₂ solution deposited on Re sample filaments in a triple-filament ion source. The relative error between calculated and experimentally determined concentrations in synthetic calcium solutions was ≤0.1%. The 95% limit of error for a single analysis was approximately 0.2% for synthetic and serum samples. A comparison of the isotope dilution data with concurrently determined atomic absorption data from several clinical and independent laboratories is presented.

6.10 Chromium

A method has been described for the determination of chromium and its enriched SI in human urine by IDMS. A volatile chelate was formed using trifluoroacetylacetone (TFA) and the fragment ions corresponding to Cr(TFA)²⁺ in the m/z 356–360 region were monitored. The chelate was thermally stable and exhibited no memory effects when the isotope ratios changed. The detection limit for the method was 0.03 ng g⁻¹ of Cr and the accuracy was verified using certified reference materials (CRMs) and by an independent method. The method was highly specific for chromium, owing to the combined properties of the chelating agent, chromatographic column and mass-specific detector. In addition to total chromium determinations, the method can also be used to quantitate enriched SIs of chromium used as metabolic tags in tracer experiments in human nutrition studies.

6.11 Iron

IDA by ion exchange has been used for the determination of traces of iron. A theoretical evaluation of this method is given, from which the conditions for the determination of a number of metals can be predicted. The selectivity of the method was further increased by the use of masking and precipitating agents. The proposed method has been verified by the determination of iron using EDTA and Dowex 50 cation exchanger. The average precision of mean values for amounts of 10⁻⁷ g of Fe per 5 mL was 1.2%, for amounts of 10⁻⁸ g of Fe per 5 mL it was 4.0% and for amounts of 10⁻⁹ g of Fe per 5 mL it was 4.1%. Even large excesses of many metals did not interfere in the analysis. The method has been applied to the analysis of NaI(Tl) crystals. The procedure which has been developed is very simple, and is far more sensitive than colorimetry, activation analysis or other methods used up to now for determining traces of iron.

6.12 Cobalt

IDA has been combined with solvent extraction and spectrophotometry to produce an effective general method for the determination of constituents that will not extract quantitatively. Combining isotope dilution with extraction of the cobalt–2-nitroso-1-naphthol complex into chloroform resulted in an accurate and reliable method for the determination of small amounts of cobalt in alloys of high copper content and in ingot irons. ⁶⁰Co was used as a radioactive tracer.

An isotope dilution method for the determination of cobalt employing ⁶⁰Co as the tracer and a spectrophotometric procedure based on the extraction of cobalt thiocyanate with methyl isobutyl ketone (MIBK) has
been developed. The extraction was carried out under neutral or slightly basic pH conditions and this made the procedure virtually specific for cobalt. The method was suitable for the determination of cobalt at concentrations from a few parts per million upwards in biological materials, vitamin B₁₂, salts, metals, etc. When a well-type scintillation detector was used for measuring the radiation of ⁶⁰Co in liquid samples, the procedure was relatively simple and rapid. The results obtained in testing the behavior of a number of metals and the various stages of the extraction of cobalt thiocyanate with MIBK in the presence of ⁶⁰Co as tracer are also presented.

**6.13 Copper**

Copper has been determined in serum samples by radio-IDA and incomplete extraction. On decomposition of serum from a venous blood sample, Cu was labeled with ⁶⁴Cu. Dithizone in CCl₄ was used for extracting Cu at substoichiometric levels. The original Cu concentration was calculated from Ruzicka's equation. The method is compared with a colorimetric method.

**6.14 Zinc**

A new separation method using ion exchange based on complexation in a resin matrix has been used for the substoichiometric determination of Zn by the isotope dilution method using a chelating agent-loaded resin. A resin loaded with 8-quinolinol-5-sulfonic acid was also shown to be applicable to the selective preconcentration of chalcophile elements in natural water samples. An additional advantage of this resin was that the ion-exchange capacity can be varied according to the desired purpose and therefore substoichiometric separation may be achieved. The possibility of the determination of zinc with substoichiometric amounts of 8-quinolinol-5-sulfonic acid was investigated.

The comparative extractability of Zn with potassium salts of ethyl, propyl, butyl, pentyl and benzyl xanthates in the pH range 3.5–9.0 into chloroform has been studied, employing a sensitive and rapid substoichiometric radiochemical method. The extent of reproducibility was tested in each case. The effect of associated ions on the extraction was studied. The amount of Zn present in the standard solutions was determined employing each xanthate separately. The Zn content present in geological water samples in and around Tirupati was determined by the method developed and compared with the values obtained by atomic absorption spectroscopy (AAS).

**6.15 Arsenic**

Arsenic has been determined in biological and environmental standard reference materials (SRMs) by substoichiometric solvent extraction using toluene-3,4-dithiol in benzene. A radiochemical solvent extraction procedure has been developed for the determination of As(III) using ⁷⁶As tracer. It is based on the complexation of As(III) with toluene-3,4-dithiol at pH 2 and subsequent extraction in benzene. The effects of various parameters such as pH, time of equilibration, nature of solvent, quantitative character and interferences were studied. The method has been further developed into Subst-IDA for the determination of As at <1 mg levels and employed for the analysis of several environmental and biological SRMs from the National Institute of Standards and Technology (NIST) (USA), the International Atomic Energy Agency (IAEA) (Vienna) and NIES (Japan).

**6.16 Selenium**

Selenium has been determined in plant materials by a fluorimetric method employing ⁷⁵Se. An exhaustive chemical procedure is described. A 0.05% solution of purified naphthalene-2,3-diamine in 0.1 M HCl (0.5 mL) was employed for the fluorimetric method. The fluorescence was compared against a reagent blank. The isotope dilution results were used to correct for losses during the combustion and extraction. Of 20 metal ions tested, serious interference was observed from Cr³⁺, Sn⁴⁺ and Sb³⁺. The standard deviation (SD) for the determination of 0.2 μg of Se was 0.04 μg.

The determination of Se by the SSE method of IDA involves the extraction of a test solution of Se labeled with ⁷⁵Se. Sodiumdiethyldithiocarbamate was used as reagent and CCl₄ as a solvent. The activity was counted on an NaI(Tl) detector. The Se concentration was calculated from a calibration graph of concentration against the ratio A to A' where A = activity in the organic phase and A' = repeated measurement in a fresh aliquot. For 1.92 ppm of Se, the SD was 0.1371 ppm.

A method is described for the determination of 10⁻² ppm levels of Se in organic samples. The method consists of a micromodification of the spectrophotometric method employing 3,3'-diaminobenzidine as reagent for extracting selenium(IV), and incorporates an isotope dilution technique to compensate for the unavoidable losses that occur during the course of the determination of Se.

**6.17 Silver**

Isotope dilution electroanalysis has been used for the determination of silver at microgram levels. The method consists in electrolysis at a controlled potential with a silver-wire cathode and a platinum wire anode and the measurement of the specific activity of the Ag deposited on the cathode. Two microelectrolysis cells were connected in series, one containing an amount
of inactive Ag (x) plus a known amount of $^{110}$Ag (y) and the other containing the same amount (y) of $^{110}$Ag. In the presence of Cu$^{2+}$, Ni$^{2+}$ and Cd$^{2+}$, Ag may be determined in the range $10^{-3}$–$10^{-6}$ g mL$^{-1}$ of electrolyte with a coefficient of variation of 2.3% at the $10^{-7}$ g mL$^{-1}$ level.

6.18 Cadmium

Cadmium has been determined in SRMs. The method involves four polyethylene samples with nominal Cd contents from 40 to 400 ppm, which were supplied as small wire cuts each of about 10 mg. Each sample was mixed for 1 h and bottled in 30 g units. Homogeneity was tested by taking 15 pieces of 60–250 µg from each of the four bottles and analyzing them by solid-sampling Zeeman-corrected AAS, with measurement at 326.1 nm. These results were tested statistically. Samples VDA-001, -002 and -003 gave normally distributed results and homogeneity factors and minimum representative sample weights (13–27 mg) were calculated. The fourth sample, VDA-004, was not normally distributed, with sample weights (13–27 mg) were calculated. The fourth sample was oxidized with H$_2$SO$_4$–HNO$_3$–H$_2$O$_2$, the Cd was plated on to Pt and were determined by IDMS. Samples were oxidized with a coefficient of variation of 2.3% at the $10^{-7}$ g mL$^{-1}$ level.

6.20 Antimony

A rapid and selective substoichiometric radiochemical method has been developed for the determination of microgram amounts of antimony employing potassium ethyl xanthate as a reagent and chloroform as an extractant from sulfuric acid medium. The effect of associated ions on the extraction was studied. The method developed was successfully applied to determine the antimony content in standard solutions and synthetic mixture with an average error of ±0.07%.

6.21 Tellurium

A radiometric method based on redox substoichiometry has been developed for the determination of tellurium. The oxidation of tellurium(IV) to tellurium(VI) with potassium dichromate was employed as the substoichiometric reaction, followed by tributyl phosphate extraction of the unreacted tellurium(IV) for substoichiometric isolation. The oxidation of tellurium(VI) with dichromate under the substoichiometric conditions was incomplete. The chemical yield of tellurium(VI) produced by the oxidation of tellurium(IV) with dichromate was 83%. It was found that a tellurium content of 50–160 µg could be determined with an accuracy of ±1.3% by means of the comparison method.

6.22 Iodine

A Subst-IDA method was developed for the determination of iodine in different brands of common salt. An aqueous salt solution containing $^{131}$I tracer and NaI as carrier was oxidized by tartaric acid and KIO$_3$ and the liberated iodine was extracted with CCl$_4$. To the extract an aqueous solution of AgNO$_3$ was added in stoichiometric amount to obtain a colloidal solution of AgI. On adding sodium thiosulfate solution, the NaI so formed passed into aqueous solution, which was then counted. Several different brands of salt were analyzed. The method was especially suitable for the determination of microgram amounts of iodide in the presence of excess of chloride.

6.23 Lanthanum

The Subst-IDA method has been used for the determination of La in environmental samples using cupferron in chloroform. Dried powder was fused with sodium peroxide and 99.9% scandium oxide as holdback carrier. The fusion mixture was allowed to melt with occasional stirring, the resulting cake was cooled in H$_2$O$_2$ and 6 M HCl before dilution with water. The $^{140}$La tracer was treated with La carrier solution, water and 0.02 M aqueous cupferron. Ammonium buffer of pH 9.0 was added.
and the resulting solution was shaken with chloroform for 2 min. After equilibration, a brown-red complex was formed with clear phase separation. A portion of the organic and aqueous phases were counted at the 2487 and 1596 MeV photopeaks of $^{140}$La using an NaI(Tl) well-type detector in conjunction with a multichannel analyzer (MCA). The calibration graphs were linear for 22–550 ng and 1.75–44 µg of La. The method was applied substoichiometrically to four cement dust particulate samples and SRMs of environmental importance; the relative SD was <8%. Interference masking and elimination methods are discussed.

6.24 Hafnium

Hafnium has been determined in Zr-4 and Zr-6 zirconium metal standards by stable IDA. Hf values obtained for Zr-4 and Zr-6 standards were 77.4 ± 3.9 (tentative) and 166 ± 17 ppm, respectively.

Hafnium has been separated from zirconium by a chromatographic method and determined by IDA. The method is based on the different stabilities of the sulfate complexes. The best separation was obtained by using 0.65 N H$_2$SO$_4$ for washing the cationic column. With 0.7 N H$_2$SO$_4$ the separation was significantly quicker, although not quantitative, but this did not interfere with the method of isotope dilution. The relative error was <1% of Hf in mixture containing approximately 10% of Hf, but higher if the Hf concentration was <3%. The method was used for the determination of Hf in eudialyte and Zr and also in mixed oxides of Zr and Hf of various concentrations.

6.25 Tungsten

An isotope dilution procedure using $^{185}$W for the determination of W in high-alloy steels has been described. Tungsten was determined spectrophotometrically with quinol in H$_2$SO$_4$ after homogeneous precipitation from HNO$_3$–H$_2$O$_2$. No further chemical separation was required for Mo–V–W steels, but for steels containing Nb, Ta and/or Ti, chemical separation of the elements that would interfere with subsequent spectrophotometric determination was necessary. The method was successfully tested on a number of National Bureau of Standards (NBS) steels to which various amounts of Ta and Ti were added.

6.26 Rhenium

Rhenium has been determined by a surface ionization isotope dilution method. Down to 1 µg of Re can be determined by MS by heating (at 2200 °C) a tungsten filament on which the metal has been deposited. Re in 10 mg samples of Re–W alloys (3–25% of Re) has been determined by an isotope dilution method (with use of $^{187}$Re) with a SD of ±2%.

A radiotracer method has been used for the determination of Re. Radiometric correction and interpolation methods have been suggested for rhenium determination using a $^{188}$Re (16.9 h) radiotracer. The radioactive isotope was obtained in an $^{188}$Re generator consisting of a glass column filled with aluminum oxide with a parent isotope $^{188}$W (69.4 days) firmly adsorbed. The isotope $^{188}$Re formed was eluted from the generator with a 0.9% solution of sodium chloride. Isotopic equilibrium among stable and radioactive rhenium (in the form of perrhenate ions) was obtained just after mixing the two solutions. A scintillation detector with a NaI crystal was used for γ-counting.

Rhenium has been extracted with a tetraphenylphosphonium complex into dichloroethane. Liquid scintillation counting was used. By this method, 1–100 µg of rhenium(VII) in the analyzed sample was determined. The relative SD was 0.05–0.09% over the whole concentration range.

6.27 Gold

Gold has been determined by radioactivation analysis accompanied by the isotope dilution method. The sample (containing $M_x$ of the element to be determined) and the standard (containing $M_y$) were irradiated under identical conditions and then each was mixed with a large amount of carrier, an aliquot was separated and their activities $A_x$ and $A_y$ were measured. The value of $M_x$ is expressed by $M_x = M_y A_x / A_y$. This relationship has been exemplified by the determination of Au (0.03–3.4 ppm) in metallic Cu with rhodamine B (Cl Basic Violet 10) solution as extracting agent.

6.28 Mercury

IDA by solvent extraction has been employed for the highly selective determination of trace amounts of Hg. Mercury has been determined in amounts of $10^{-6}$–$10^{-7}$ g mL$^{-1}$ with an average precision of ±0.5% and in amounts of $10^{-8}$–$10^{-9}$ g mL$^{-1}$ with an average precision of ±2.5%. The determination of smaller amounts of mercury was subject to large errors because of the lower specific activity of the radiomercuromy employed. In the analysis, even significant excesses of metals which also form extractable complexes with dithizone do not interfere. The method is very rapid and simple, because it consists of a single extraction of the analyzed solution and measurement of the activity of the extract. The procedure developed is far more precise and sensitive than the colorimetric method.

A new principle for the substoichiometric determination of traces of Hg by IDA has been reported.
method was based on the dithizone–carbon tetrachloride extraction of Hg from the test solution (e.g. a solution of an ore or a mineral water). The necessity for determining the chemical yield was avoided. The main advantage of the isotope dilution method is the use of low activities.

Malonic anilide has been employed for the substoichiometric extraction of Hg into a mixture of ether and MIBK and for the subsequent determinations in industrial effluents from the Durgapur area, W.B., India.\(^{(56)}\)

A radiometric method based on Subst-IDA has been developed for the determination of trace amounts of Hg using \(\alpha\)-thiopicolin-\(o\)-anisylamide as a substoichiometric reagent.\(^{(57)}\) A preconcentration procedure has also been developed based on the adsorption of Hg(II) as a dithizone complex on microcrystalline naphthalene which, when used in conjunction with the proposed radiometric method, enhances its sensitivity and selectivity. As little as 0.2 \(\mu\)g of Hg could be determined in an aqueous phase of 80 mL. The method has been successfully applied to the determination of trace amounts of Hg in city waste incineration ash, zinc metal and cadmium oxide samples.

6.29 Thallium

Thallium has been determined by SSEIDA.\(^{(58)}\) The general method has been applied to the determination of Tl. A constant substoichiometric amount of EDTA was used, and the unchelated Tl\(^{3+}\) was removed by precipitation with aqueous ammonia before an equal volume of the solution was removed for counting. Common anions did not interfere, and interfering cations were eliminated by extracting Ti(III) from 6 M HCl into diethyl ether.

Thallium has been determined using brilliant green by SSEIDA.\(^{(59)}\) The 1:1 complex between TlCl\(_4\) and the brilliant green (I) cation was extracted into benzene; this avoided the need for large excess of the reagent and yielded a stable colour with a high \(E\) value. In this subequivalence test, the aqueous medium, containing radioactive plus inactive Tl (carrier), was made 2.5 M in HCl, I was added in substoichiometric amount and the extraction was carried out for 9 min. The benzene extract was evaporated and the residue was counted with a Geiger–Müller tube. In the superequivalence variant, twice as much radioactive (but no inactive) Tl and more I was used. The amount of active Tl was found from the point of intersection of isotope dilution curves. For 0.5–105 \(\mu\)g of active Tl(III), the errors ranged from \(\pm 1.2\) to 2.3\%. Preliminary extraction of Tl into diethyl ether from 6 M HCl medium and washing the extract with 3 M HCl prevented interference from Fe(III), Ga(III) and In(III). Interference from Au(III) and Sb(V) was avoided by reducing these with metallic Cu before extraction. Sulfate, nitrate and acetate interfered in the formation of the Tl complex.

6.30 Lead

Ultramicro amounts of lead have been determined by IDMS.\(^{(60)}\) After isotopic equilibration with approximately 0.5 \(\mu\)g of \(^{208}\)Pb, the sample, e.g. pure water or snow (20–100 g), was mixed with silica gel (13 \(\mu\)g) and H\(_3\)PO\(_4\) (127 \(\mu\)g) as stabilizing agents, and part of the mixture was loaded on to a rhenium filament for MS. The Pb concentration of the sample was calculated from the ratio of \(^{206}\)Pb\(^+\) to \(^{208}\)Pb\(^+\). The coefficient of variation was approximately 3\% for several measurements of added \(^{208}\)Pb (0.003–1.8 \(\mu\)g), 3–7\% for river water (approximately 0.07 ppb) and 1.3\% for mountain snow (0.86 ppb). The instrument produced 1 fA of ion current from each nanogram of added \(^{208}\)Pb\(^+\), the detection limit being 0.1 aA. The method was also applicable to the analysis of reagents, e.g. ammonia solution, hydrochloric acid and perchloric acid.

The application of displacement and exchange reactions in IDA of Pb has been studied.\(^{(61)}\) The efficiency of separation of metal ions combining a displacement or exchange reaction and a liquid–liquid extraction procedure was calculated as a function of parameters such as pH, the ratio of the concentration of reagent and analyte and the ratio of the concentration of reagent and interfering ions. The resulting equations can be used to calculate favorable conditions for multielement IDA.

6.31 Uranium

A procedure and instrumentation for the automatic measurement of isotopic ratios with a double collector magnetic mass spectrometer have been used for U-isotope analysis.\(^{(62)}\) Essentially, measurement was achieved by discriminating in favor of the desired peak plateau for ion current integration during the high-voltage variation. The peak resolution was virtually unaffected by off-set drift in the electronic system. Before each ratio measurement, the off-set values were determined and digitally stored for final compensation when isotopic ratios were calculated with an arithmetic unit.

Traces of uranium have been determined in metallic sodium by IDA and a spectrophotometric method.\(^{(63)}\) Sodium (5 g) was evaporated (within 5 h) at a pressure of 10\(^{-4}\) Torr at 350°C in a stainless-steel crucible. There was no loss of U (approximately 1 \(\mu\)g) under these conditions. An isotope dilution method was used to determine 0.001–1 ppm of U with the use of an NBS standard isotope. For >1 ppm of U, the U was reduced with Zn amalgam to U(IV), which was determined spectrophotometrically with arsenazo III after extracting...
Fe(III) with diethyl ether. No interference was caused by the small amount of Fe dissolved from the crucible.

6.32 Plutonium

Plutonium has been determined in a NIST SRM by IDA. The SRM 4351 human lung was acknowledged to be inhomogeneous. The value of a single analysis for $^{239}$Pu + $^{240}$Pu could lie within a wide range, but the accuracy of the analysis can be corroborated by comparing the corresponding $^{238}$Pu/$^{239}$Pu + $^{240}$Pu or $^{239}$Pu/$^{240}$Pu values with the relationships between these ratios and the total plutonium concentration. The $^{238}$Pu/$^{239}$Pu + $^{240}$Pu ratio was reported by activity and the $^{240}$Pu/$^{239}$Pu ratio by atoms in aliquots of the SRM 4351. The data give an experimental insight into the inhomogeneity of the material, augmenting the purely statistical indicators that have existed so far. An intercomparison exercise on $^{239}$Pu + $^{240}$Pu in SRM 4351 was carried out. The objectives were to evaluate the capabilities of the participating laboratories for Pu measurements in human tissues and to improve the characterization of the $^{239}$Pu + $^{240}$Pu concentration value for the SRM. The results were published, but the values of $^{239}$Pu and of $^{240}$Pu as distinct from $^{239}$Pu + $^{240}$Pu figures were not reported.

7 APPLICATION OF ISOTOPE DILUTION ANALYSIS TO SOME MULTIELEMENTAL DETERMINATIONS

IDA has been used for the certification of SRMs. Isotope dilution has been applied at the NBS, employing thermal ionization or spark source MS, to determine accurately the concentration of trace elements in natural materials. These techniques have been applied, in conjunction with separation by ion exchange, chelation by resins, electrodeposition and chemical extraction. The certification of a range of biological and environmental SRMs, including the contents of Pb and trace elements in water, 15 elements in coal and fly ash, U in bovine liver and Hg in water, is presented.

IDA has been used for the trace analysis of microelectronically relevant heavy metals in high-purity titanium. Because titanium is increasingly used in microelectronic devices, an IDMS method has been developed for the reliable determination of traces of U, Th, Cu, Pb, Cd, Cr, Ni and Fe in high-purity titanium primary materials. The measurement of isotope ratios was carried out with a thermal ionization quadrupole mass spectrometer using positive thermal ions formed by a single- or double-filament ion source, except for thorium, where an ICP mass spectrometer was applied. Different separation techniques (ion exchange, chromatography, extraction, electrolytic deposition, coprecipitation) were used for the trace element–matrix separation and for the specific isolation of the trace elements to be determined. The detection limits obtained were U, Th = 0.07, Cu = 1, Cd = 1.7, Ni = 4, Pb = 6 and Fe = 35 ng g$^{-1}$. Three titanium samples of different purity were analyzed with concentrations in the following ranges: U, Th = $<0.07 \times 10^{-3}$–0.09, Cd = $<0.002$–0.7, Cu, Ni, Pb, Cr = 0.01–30 and Fe = 7–6 × 10$^4$ ng g$^{-1}$. The IDMS results for one titanium sputter target were compared with those for two different laboratories which showed the urgent necessity for the application of independent and reliable analytical methods.

Multielemental IDA by means of radiometric titration for the determination of Cu and Pb has been discussed. A theoretical concept was derived for multielement IDA in a liquid–liquid extraction system. The practical performance was based on radiometric titration. For this purpose, a prototype of a titration/extraction vessel with flow injection was constructed. For calculations of the initial concentrations of the elements of interest from the experimental data, a computer program was developed.

Niobium and tantalum have been quantitatively determined by IDA. Preliminary separations of Nb and Ta from each other and from Ti and Zr can be made by precipitation with benzene–selenium acid and extraction with 8-hydroxyquinoline before determination by means of the radioactive isotopes $^{95}$Nb and $^{182}$Ta. Nb was separated from Zr in 1 M HCl containing 0.5% of citric acid and 1.5% of ammonium selenate and Ta from Zr by increasing the citric acid concentration to 1.5%. Nb was separated from Ta, Zr and Ti by extraction at pH 4.0 to 4.5 with 2% 8-hydroxyquinoline solution in chloroform.

Uranium–plutonium metallic spikes for IDMS accountancy measurements, preparation and characterization have been discussed. The advantages were discussed of the use of a solid $^{233}$U–$^{239}$Pu alloy rather than the conventional $^{233}$U–$^{242}$Pu solution to provide tracers for the IDMS determination of U and Pu in spent nuclear fuel solutions for reprocessing. The compositions [all percentages (w/w)] U–0.5% Pu–50% Ti, U–0.5% Pu–25% each Nb and Zr and U–1.0% Pu–2.3% Nb were chosen on account of their good cold formability, and were prepared by inductive levitation melting, subsequently being cold-rolled to a thickness of approximately 0.1 mm. Metallography of these alloys showed no significant heterogeneity, and X-ray spectrometry showed that the relative SD of the Pu distribution in portions composed of 0.1 g of U and 1 mg of Pu (the usual added masses) was 0.4% for the U–Pu–Nb–Zr alloy and 0.1–0.2% for the other two.

Sample preparation approaches have been discussed for the IDICPMS certification of reference materials. The application of IDA to inductively coupled plasma...
mass spectrometry (ICPMS) is discussed. The requirements for accurate sample preparation and instrumental analyte–matrix–plasma interaction for the attainment of precise isotope ratio measurements are presented. The method is illustrated by the determination of Mg, Cd, Mo and Pb in synthetic samples, Cu and Cd in Zn ore and Cu and Mo in sewage sludge. The integration of procedures into the certification program at NIST is described.

Simultaneous radiochemical determination of chemically similar elements by the concentration-dependent distribution method has been described.(71) The method with two substoichiometric systems can be characterized by the following features. The selectivity of the two systems must be different, and desirably each of them should react preferentially with a different element. It is sufficient to use only one tracer for the two systems, but the use of two tracers could be advantageous in some cases. The analysis is based on the fact that if phase distributions in the two systems occur under strictly standard conditions, a set of two distribution ratios corresponds to the two values of the unknown concentrations. The calculation of the unknown concentrations from the two distribution ratios can be carried out using (i) theoretically derived equations based on the equilibria involved, (ii) empirical or semiempirical relationships and (iii) calibration plots. The calibration plots can be used in any case; methods (i) and (ii) can be utilized under conditions required for sufficiently strict validity of the corresponding equations. The method was applied for the determination of Rb and Cs.

The partial isotope separation of U and Fe by means of solvent extraction has been discussed.(72) The separation of isotopes is of great practical importance and, hence, it is worthwhile to explore the possibility of isotope separation by means of the simple method of solvent extraction.

Subst-IDA has been applied for the determination of trace elements in liquid samples, of the carrier content in RI solutions and of concentrations of organic reagents.(73) Cu in mineral acids and in a ZnSe single crystal was determined by substoichiometric extraction with dithizone. Values of 1.8 and 0.018 ppm in nitric acid and of 1.4 and 0.44 ppm in ZnSe were obtained. Cu and P carrier contents in 65Cu and 32P solutions were determined by substoichiometric extractions with dithizone in carbon tetrachloride and with molybdc acid into MIBK in a series of solutions, adding various amounts of Cu and P carrier. An analogous method was applied for the analysis of dithizone and diethylthiocarbamate solutions. The method was also applied to the determination of 60Co radioactivity in environmental samples. The analytical results for water samples are described.

Molybdenum and nickel have been determined in SRMs using the internal normalization technique for high-accuracy IDA.(74) General exact equations and iteration techniques have been developed for internal normalization to eliminate the effect of thermal fractionation on isotope ratio measurements, and therefore IDA, by thermal ionization MS. The techniques were applicable to more than 20 elements, and have been extensively applied to the determination of Mo in ore concentrates (55% Mo) and silicate trace standards (50 and 500 ppm Mo). The SD of all internally corrected Mo isotope ratio measurements was 0.1%. The Mo sample size was 40 µg, but the normalization technique should apply to microgram and smaller samples with a more sensitive ion detection system. Procedures are described for the chemical separation of Mo from matrix interferences and for the MS determination of Mo. Application of the techniques to Ni in three pollution SRMs is described.

A new variation of IDA based on double labeling carried out on filter-paper has been described.(75) The determination of microgram and submicrogram amounts of silver (labeled with 110mAg) by precipitation with iodide (labeled with 131I) and of Ca (labeled with 45Ca) by precipitation with phosphate (labeled with 32P) are given as examples. In the first example, the two radionuclides (110mAg and 131I) were measured by γ-spectrometry and in the second method (45Ca and 32P) by a β-absorption method. The results show the usefulness of the method.

Coprecipitation has been used as a means of separation in Subst-IDA.(76) It is shown with examples that by applying coprecipitation for separation and by using complexometric and oxidimetric or reductometric reactions as the substoichiometric reaction, a wide range of complexometric determinations of metal ions (e.g. with EDTA) and many types of redox determinations are opened up for further investigation. The method is simple, not time-consuming and offers many possibilities owing to the freedom to select a suitable precipitate.

A semiquantitative method of isotope dilution in the microgram and submicrogram ranges using the ring oven method has been described.(77) Radioactive tracer elements were added to the sample solution and separated by the ring oven technique. The separated ring of precipitate was counted and the original concentration determined from a calibration graph. Examples are cited for the determination of calcium, iron and phosphate.

Ca and Mg have been determined by isotope dilution at the microgram level.(78) Natural calcium contains 96.97% of 40Ca and 2.06% of 44Ca and the tracer isotope used contained 2.9% of 40Ca and 97% of 44Ca. Precautions were necessary to avoid contamination, e.g. from atmospheric dust and from the vessels used. A solution of known concentration (1 mL) mixed with a known amount of tracer isotope was evaporated under nitrogen to one drop, which was applied to the double Ta filament of the spectrometer and evaporated to dryness.
The residue was covered with ammonium oxalate (as ionization activator) by similar evaporation of three drops of a saturated solution, and the ratio of the two isotopes was determined. Amounts of approximately 1µg of Ca could be determined readily with a SD of 2.5%. The sensitivity under the conditions used was approximately 0.01µg. Determination of 10^-4 – 10^{-5} µg is considered possible. Interference due to 40K can be eliminated by heating the filament to a temperature below that necessary for the determination of Ca. Natural Mg (78.6% of 24Mg and 10.11% of 25Mg) was determined by mixing Mg(NO₃)₂ solution (1 mL) with the tracer isotope (98.5% of 25Mg) and BeO (1 mg) as activator, and applying the concentrated solution to a double rhenium filament. From solutions containing 30.34 and 3.034 µg mL⁻¹ of natural Mg, recoveries were 30±0.44 and 3±0.016±0.086 µg mL⁻¹, respectively. Under suitable conditions, the measurement of approximately 10⁴µg was considered possible. Use of a double instead of a single filament increased the sensitivity approximately 100-fold.

Application to the determination of elements and chemical compounds by SI dilution has been reported. A review is presented on the use of this technique for the determination of H, rare gases, C, N, O, S, alkali, alkaline earth and heavy metals, the actinium series and compounds containing these elements.

ACKNOWLEDGMENTS

Thanks are due to Dr J.P. Mittal, Director, Chemical Group, BARC and Dr D.D. Sood, Director, Radiochemistry and Isotope Group, BARC for some of the papers on IDA required for this work. Sincere thanks are due to Shri Taher for typing the manuscript in spite of his busy schedule.

Analysis of the elemental content of a sample by irradiation with neutrons and measurement of the induced radioactivity are described.

1 INTRODUCTION

Chemical analysis by nuclear activation is an elemental analysis, i.e. it determines the contents of the various elements in the analyte sample, but cannot tell in what chemical form (compounds, valence states, etc.) they are present. The analysis is based on a reaction of the analyte element with nuclear projectiles (neutrons, accelerated small charged particles, e.g. protons, or \(γ\)-photons) [Equation 1]:

\[
\text{target + projectile} \rightarrow \text{light product + heavy product}
\]

(1)

In instrumental neutron activation analysis (INAA) the projectile is a thermal neutron and the measurement of the concentration of the element is done via the heavy product, if it is a radionuclide which emits \(γ\)-rays. The amount produced of the radionuclide is proportional to the number of the target atoms.

2 BASIC NUCLEAR PHYSICS

This section gives only a brief description of basic knowledge. Readers who are interested in further detail should consult common textbooks.\(^{1–6}\)

2.1 Radioactive Decay

Most radioactive decays occur via the transformations neutron \(→\) proton and proton \(→\) neutron and are called \(β\)-decays. They are characterized by the mass number, \(A\), which remains unchanged, whereas the atomic number is changed by \(\pm 1\). There are three transformations of this type. A neutron is transformed into a proton by a \(β^-\) process [Equation 2]:

\[
n \rightarrow p^+ + β^- + ν
\]

(2)

The proton remains in the nucleus, whereas the electron \((β^-)\) and the antineutrino \((ν)\) are emitted from the nucleus, with high kinetic energies. The electron is written as \(β^-\) and not \(e^-\), to show that it is not an atomic electron.

A proton can be transformed into a neutron by two processes. One process is \(β^-\) decay, in which a proton is transformed into a neutron and a positron \((β^+ = e^+)\), an entity similar in mass to an electron but which has an opposite charge [Equation 3]:

\[
p^+ \rightarrow n + β^+ + ν
\]

(3)
In this process there is also an emission of a neutrino (ν). Another process is the reaction of a proton with one of the surrounding electrons in the atom to yield a neutron. This process is called electron capture (EC). The neutrino and antineutrino are very small particles with no charge, and consequently they are very difficult to detect. They are not important in activation analysis, except for their effect on the β energies, which will be explained later.

Most radionuclides are not pure β emitters, but they emit simultaneously also a γ-photon (more accurately, the γ emission occurs in a very short time of <10^{-10} s after the β- emission). γ-Rays are electromagnetic waves, like light and radio waves, but they have much higher energies (much shorter wavelengths). They have usually higher energies than X-rays, although the main difference between X-rays and γ-rays is their sources. X-rays are due to atomic transitions (transitions between different energy levels of electrons), whereas γ-rays are due to nuclear transitions (transitions between different energy levels of the nucleons). In most cases β^- decay does not yield the ground state of the product nuclide, but forms it in an excited state. The excited-state nuclide decays very rapidly (in most cases) to the ground state by the emission of either γ-rays or atomic electrons called conversion electrons. The emitted conversion electrons have no importance in activation analysis and we can neglect their emission and refer only to the emission of γ-rays.

A very important difference between β processes and γ decay (besides the difference in entities of the emitted particles, electrons vs photons, and the difference in ΔA, ±1 in the β process and 0 in the γ decay) is the fact that in β processes there is emission of two particles, β^- and ν or β^+ and ν, whereas in γ decay there is emission of only one photon. There are cases of the emission of a few photons from the same nuclide, but these are successive emissions and not a simultaneous emission as in the β processes. The importance of this difference lies in the fact that each nuclear decay is a transformation between two discrete energy states, resulting in a definite energy released in the process. If only one particle is emitted from the nucleus, this particle has a defined energy. When two particles are emitted, the released energy is distributed between them, and each particle can have a spectrum of energies ranging from zero up to a maximum energy, equal to the released energy. Since the emitted γ-rays have definite energies, they can be used in order to identify their emitters, by the measurement of the energy of the photons. As β^-particles do not have definite energies, they usually cannot be used to identify their emitters.

In INAA, we need to identify the different radionuclides (in order to know the nuclide from which they were formed), in addition to the measurement of their activities. This is the reason why INAA employs almost exclusively the measurement of the spectrum of emitted γ-rays. In a few cases, where the indicator radionuclide (IRN) is a pure β^- emitter, it can be measured only in cases where there are only few (2–3) nonspecific γ-emitter IRNs in the sample with different half-lives. Their separate activities can be measured by measuring the activities at different times (measuring the decay curve) and extracting the various activities from the time dependence of the measured activity.

We said that the γ-photon emitted are due to the de-excitation of the nuclide produced in the β process. However, this de-excitation does not always have to be by only one photon. Moreover, not all β decays lead to the same level of excitation. These two facts together with the de-excitation by emission of conversion electrons (mainly from low-lying levels) lead to the possibilities that one radionuclide can have more than one kind (energy) of photon and that the number of photons should not be equal to the number of nuclides which have decayed (disintegrated). The number of photons of specific energy emitted per 100 disintegrated nuclides is called the intensity of the γ line, expressed as a percentage. Let us consider different cases of γ line intensity in four examples of radionuclides.

1. **28Al** decays completely to the 1.778 MeV excited state of **28Si**. This level decays to the ground state by only one photon. This means that **28Al** has only one γ line of 1.778 MeV with an intensity of 100%. This can be expressed by a diagram (called a decay scheme) of decreasing energies as shown in Scheme 1.

![Scheme 1](https://via.placeholder.com/150)

2. **24Na** decays almost completely (>99.8%) to one level of **24Mg** (Scheme 2). However, this level decays to the ground state only by two successive photons. The first photon of 2.75 MeV is followed by a second photon of 1.39 MeV. This decay scheme explains why **24Na** has two γ lines of 2.75 and 1.39 MeV, each with almost 100% intensity.

3. **27Mg** decays to two different excited levels, resulting in two β^- with different energies, 1.59 MeV (31%) and 1.75 MeV (69%) (Scheme 3). The higher excited level (1.01 MeV) decays only 98% directly to the
4. $^{38}$Cl decays directly to three different states of $^{38}$Ar, both to two excited states of $^{38}$Ar and to the ground state of $^{38}$Ar (Scheme 4). This is the reason for $^{38}$Cl having three different energy $\beta^-$ particles (remember, it is only maximum energy, since $\beta^-$ leads to a spectrum of $\beta^-$ energies, up to $E_{\text{maximum}}$). $4.81$ MeV (53%), $2.77$ MeV (9%) and $1.77$ MeV (38%). The higher excited state ($3.77$ MeV) decays almost completely to the lower excited state. The lower excited level decays to the ground state while 2% ($0.31 \times 0.02 = 0.006 = 0.6\%$ from the total nuclides disintegrated) decays to the lower excited state. The lower excited level decays completely to the ground state by one photon. This decay scheme explains why $^{27}$Mg has three $\gamma$ lines of $1.01$ MeV (31%), $0.84$ MeV (69%) and $0.18$ MeV (0.6%).

2.2 Kinetics of Decay of Radioactive Nuclides

The decay of radioactive nuclides is a statistical process. Thus, the number of atoms decaying per unit time (rate of decay) is proportional to the number of atoms of that specific radionuclide present in the sample. If the number of nuclei (atoms) of a specific radionuclide at time $t$ is $N^\ast$, their rate of disappearance (decay or disintegration) is given by Equation (4):

$$\frac{dN^\ast}{dt} = \lambda N^\ast$$  \hspace{1cm} (4)

The constant $\lambda$, which is different for each radionuclide, is called the decay constant of this radionuclide. Integration of Equation (4) leads to the decay equation of radionuclides, i.e., the equation describing the time dependence of the number of atoms of the specific radionuclide [Equation 5]:

$$N^\ast(t) = N^\ast_0 e^{-\lambda t}$$  \hspace{1cm} (5)

where $N^\ast_0$ is the number of atoms at time chosen as $t = 0$. Equation (5), which is the same as the integrated equation of any first-order chemical process, indicates the existence of a constant lifetime for the half of the atoms, which is called the half-life. It means that independently of the value of $N^\ast_0$, it takes the same time (for a specific radionuclide) for disintegration of half of the atoms, leaving only $N^\ast_0/2$ atoms of that radionuclide. Substituting $N^\ast(t)$ by $N^\ast_0/2$ in Equation (5) leads to the correlation between the half-life ($t_{1/2}$) and the decay constant ($\lambda$) [Equation 6]:

$$t_{1/2} = \frac{\ln 2}{\lambda} = \frac{0.693}{\lambda}$$  \hspace{1cm} (6)

Equation (5), the decay equation, can be written also with $t_{1/2}$ instead of $\lambda$ [Equation 7]:

$$N^\ast(t) = N^\ast_0(0.5)^{t/t_{1/2}}$$  \hspace{1cm} (7)

The advantage of Equation (7) over Equation (5) is in that it gives a better ‘feeling’ for the extent of the decay. Thus, for example, if the half-life is $t_{1/2} = 2.5$ days, we know that after 2.5 days only half of the original atoms remain, and after 5 days the number of original atoms is reduced to one quarter. Equation (5) was easier to use when people were using tables of exponents. Nowadays
with computers there is no difference which equation is used. In tables of data, only \( t_{1/2} \), the half-life, is given. In order to use Equation (5), \( \lambda \) should be calculated from Equation (6).

2.3 Kinetics of Chain Decays

In some cases a radionuclide decays not to a stable nuclide but to another radionuclide setting a chain of decays. Each chain is terminated in a stable nuclide. For a chain of decays as shown in Equation (8):

\[
\begin{array}{c}
R_1 \\ \lambda_1 \\ \cdots \\ \lambda_n \\
\cdots \\
R_n \\ \lambda_n \\
\end{array}
\rightarrow \\
R_2 \\ \lambda_2 \\
R_3 \\ \lambda_3 \\
\vdots \\
S
\]  
(8)

where \( R \) denotes a radionuclide and \( S \) stands for a stable nuclide. For the Bateman equation [Equations 9 and 10]:

\[
R_n = C_1 e^{-\lambda_1 t} + C_2 e^{-\lambda_2 t} + \cdots + C_n e^{-\lambda_n t} \]
(9)

\[
R_n = \sum_{i=1}^{n} C_i e^{-\lambda_i t} \]
(10)

where [Equations 11 and 12]:

\[
C_1 = \frac{\lambda_1 \lambda_2 \lambda_3 \cdots \lambda_{n-1} N_1^0}{(\lambda_2 - \lambda_1)(\lambda_3 - \lambda_1) \cdots (\lambda_n - \lambda_1)}
\]
(11)

\[
C_2 = \frac{\lambda_1 \lambda_2 \cdots \lambda_{n-1} N_1^0}{(\lambda_1 - \lambda_2)(\lambda_3 - \lambda_2) \cdots (\lambda_n - \lambda_2)}
\]
(12)

and generally [Equation 13]:

\[
C_k = \frac{n-1}{\sum_{i=1, i \neq k}^{n} \lambda_i} N_1^0 \left( \lambda_i - \lambda_k \right) \]
(13)

This is the solution of \( n \) simultaneous differential equations [Equations 14 and 15]:

\[
\frac{dR_1}{dt} = -\lambda_1 R_1
\]
(14)

\[
\frac{dR_k}{dt} = \lambda_{k-1} R_{k-1} - \lambda_k R_k \quad (k = 2, 3, \ldots, n)
\]
(15)

2.4 Kinetics of Formation of Radioactive Nuclides by Irradiation

When a thin target is bombarded with a beam of projectiles, the rate of nuclear transformation (the number of nuclides produced per unit time) is proportional to the beam intensity (\( I = \) number of incident particles per unit time), to the target nucleus density (\( n = \) number of target nuclei per unit volume) and to the thickness of the target (\( dx \)). The proportionality to the thickness of the target is limited to sufficiently small \( dx \), such that both the intensity of the beam and the energy of the projectiles remain practically unchanged. The proportionality constant is denoted \( \sigma \) and is called the reaction cross-section. This term comes from a simple model, assuming that each geometrical collision leads to a nuclear reaction. In this case, \( \sigma \) is the geometrical cross-section of the collision pair, \( p(r_1 + r_2)^2 \) [Equation 16]:

\[
\frac{dN^*}{dt} = \sigma \phi A \frac{dx}{N}
\]
(16)

Since the nucleus radius is a few femtometers (10\(^{-13}\) cm), the cross-sections are of the order of 10\(^{-24}\) cm\(^2\). This is the reason why it has been customary to express cross-sections in units of barns, where 1 barn (b) = 10\(^{-24}\) cm\(^2\).

Equation (16) assumes that the beam cross-section is smaller than the target size facing the beam, and consequently each projectile particle is transversing through the target. In the case that the target size is smaller than the beam cross-section, the beam intensity, \( I \), should be replaced by the product \( \phi A \), where \( \phi \) is the beam flux (number of projectile particles per unit area and per unit time) and \( A \) is the area of the target facing the beam [Equation 17]:

\[
\frac{dN^*}{dt} = \sigma \phi A n \frac{dx}{A}
\]
(17)

\( A \) dx is the volume of the target and consequently \( nA \) dx is the total number of target atoms, \( N \) [Equation 18]:

\[
\frac{dN^*}{dt} = \sigma \phi N
\]
(18)

Since we are speaking of a reaction of a specific nuclide, \( N \) is the total number of the atoms of that nuclide. Equation (18) is used mainly for irradiation in a nuclear reactor, where the target is located inside a uniform flux of neutrons. Equation (10) is used in cases of a narrow beam from charged particle accelerators.

In the case of prompt activation analysis, the only important number is the number of nuclei which were transformed by the nuclear reaction. Hence the number of nuclei transformed is given by the integration of Equation (16) or (18) over the irradiation time. However, for delayed activation analysis, the important factor is the number of nuclei decaying during the measurement period, which is delayed and done some time after the end of irradiation. In calculating the number of nuclei of the newly formed radionuclide at the end of the irradiation, it would be wrong to integrate those equations. The radionuclides are not only formed during the irradiation, but also are decaying. Combining Equations (18) and (4) leads to the complete equation for the rate of the change...
of the number of radioactive nuclei during the irradiation in a constant flux of projectiles ($\phi$) [Equation 19]:

$$\frac{dN^*}{dt} = \sigma \phi N - \lambda N^*$$  \hspace{1cm} (19)

Integration of Equation (19) with the initial condition $N^*_0 = 0$ leads to the equation for the number of radioactive nuclei at the end of irradiation for time $t_i$ [Equation 20]:

$$N^*_{\text{EOI}} = \frac{\sigma \phi N}{\lambda} (1 - e^{-\lambda t_i})$$  \hspace{1cm} (20)

where $t_i$ is the irradiation time and EOI stands for end of irradiation. In the product $\lambda t_i$, $\lambda$ should have the same units as $t_i$ whereas in the term before the parentheses the units should be the same as the time unit of $\phi$.

For cases where $\lambda t_i \ll 1 (t_i \ll t_1/\lambda)$, the term in parentheses is approximately equal to $1 - \lambda t_i$ for $\lambda t_i \ll 1$ and $N^*_{\text{EOI}}$ is equal to $\sigma \phi N t_i$, i.e. the rate of formation multiplied by the irradiation time, since the decay is negligible.

For an irradiation time that is long relative to the half-life of decay ($t_i \gg t_1/\lambda$, $t_i \gg 1$), the term in parentheses is equal to 1, which is its maximum value. This is the maximum number of nuclei which can be formed. Longer irradiation does not increase the number of radioactive nuclei, since the rate of formation by the nuclear reaction is equal to the rate of disappearance by radioactive decay. This statement assumes that $N$ does not change substantially during the irradiation, which is common for the usual values of $\phi$ ($10^{15}$ n s$^{-1}$ cm$^{-2}$), $\sigma$ (1 b) and $t_i$ (<10 days). For the extreme cases $\Delta N/N$ is still usually $<10^{-3}$. This maximum number of radionuclides formed is termed the saturation value or the number at saturation, $N^*_\text{sat}$ [Equation 21]:

$$N^*_\text{sat} = \frac{\sigma \phi N}{\lambda}$$  \hspace{1cm} (21)

The saturation value can be increased by increasing the flux of the bombarding particles or the amount of the irradiated nuclei (the mass of the target), but not by longer irradiation. Usually we speak of the mass of a specific element in the target and not of the number of atoms of this element, so it is desirable to transform $N$, the number of atoms, into $m$, the mass of specific element in the activated samples. The number of atoms $N$ in $m$ mg of element with atomic weight $M$ is $(m/M)N_A$, where $N_A$ is Avogadro’s number. In contrast to the usual chemical measurements, where all natural isotopes of the same element react in almost the same way, this is not true for nuclear activation. For example, let us consider chlorine. Chlorine has two stable natural isotopes, $^{35}$Cl with 75.77% abundance and $^{37}$Cl with 24.23% abundance. Irradiation with thermal neutrons leads to an ($n,\gamma$) reaction forming the two radionuclides, $^{36}$Cl and $^{38}$Cl. $^{36}$Cl cannot be used as IRN for activation analysis owing to absence of $\gamma$ radiation ($^{36}$Cl is a pure $\beta$ emitter) and its long half-life (the IRN is a radionuclide used for the identification and quantification of an element in activation analysis). Hence, it is not the total number of chlorine atoms that should be used in Equations (18–21) but rather the number of $^{37}$Cl atoms alone. This is done by multiplying $N$ by the abundance of the parent of the IRN (0.2423 for $^{37}$Cl). Using $f$ for the abundance, Equation (21) takes the form of Equation (22):

$$N^*_\text{sat} = \frac{m}{M} N_A f \frac{\sigma \phi}{\lambda}$$  \hspace{1cm} (22)

The number of the nuclei of the IRN at the end of irradiation is obtained from Equation (16) as Equation (23):

$$N^*_\text{EOI} = N^*_\text{sat} (1 - e^{-\lambda t_i})$$  \hspace{1cm} (23)

The measurement of the $\gamma$ activity (the rate that the $\gamma$-rays are emitted by the activated sample) is done not immediately after the end of irradiation, but rather after some time, which is called the decay time, $t_d$. The decay time (called also ‘cooling’ time) can be fairly short, being only the time required to transfer the sample from the irradiation port to the measurement station, or can be long. Long decay times are used when we are interested in IRNs with medium to long half-lives (they are also called medium- to long-lived IRNs). The high activity of the short-lived radionuclides at short times after irradiation obscures the activity of the longer lived radionuclides. Consequently, in order to measure medium- and long-lived IRNs, their measurement is delayed. This is the reason why the decay time is called also ‘cooling time’. For determining the concentrations of many elements in the sample, the $\gamma$ activity in the irradiated sample is measured several times (at least three) after different decay times. Since the number of atoms of the IRN at the beginning of the decay time is $N^*_\text{EOI}$, the number at the end of the decay period, $t_d$, is given by Equation (24) [according to Equation 5]:

$$N^*_\text{EOI} = N^*_\text{SOC} e^{-\lambda t_d} = N^*_\text{sat} (1 - e^{-\lambda t_d}) e^{-\lambda t_d}$$  \hspace{1cm} (24)

The subscripts EOD and SOC stand for end of decay and start of counting, respectively. The measurement of the $\gamma$ activity is called counting, since it is done by the counting of the pulses formed in the $\gamma$-ray detection systems, due to the interaction of the $\gamma$-photons with the detector.

The counting is done during a time $t_e$ called the counting time. The number of atoms of the radionuclides still undecayed at the end of the counting time, $N^*_\text{SOC}$, is given by Equation (25) [according to Equation 5]:

$$N^*_\text{SOC} = N^*_\text{EOI} e^{-\lambda t_d} = N^*_\text{sat} (1 - e^{-\lambda t_d}) e^{-\lambda t_d}$$  \hspace{1cm} (25)
The number of atoms decaying in the counting period \((\Delta N_c)\) is given by the difference in the number of atoms at the beginning of the counting period, \(N_{SOC}\), and the number of atoms at the end of this period, \(N_{EOC}\) [Equation 26]:

\[
\Delta N_c = N_{SOC}^* - N_{EOC}^* = N_{sat}^*(1 - e^{-\lambda_1 t})(1 - e^{-\lambda_2 t})
\]

(26)

The actual number of events of decay recorded by the detection system, is smaller than \(\Delta N_c\), owing to three different factors: (i) the intensity of the specific \(\gamma\) line (number of photons emitted per 100 atoms decayed) is in many cases \(< 100\%\); (ii) not every \(\gamma\)-photon emitted reaches the detector, as the photons are emitted isotropically and only those in the direction of the detector will hit the detector; and (iii) some of the photons reaching the detector will not interact with it, and others will lose only part of their energy in the detector, and consequently will not be recognized as originating from the specific IRN. The last two factors are combined in a factor called the geometric efficiency of the detector, \(\varepsilon\). This factor depends on the detector, the energy of the \(\gamma\) line and the distance of the sample from the detector. For large samples, \(\varepsilon\) depends also on the sample size. The factor \(\varepsilon\) is determined experimentally by counting the activity of calibrated standards (which can be bought commercially), for which the rate of disintegration is known accurately. The rate of decay of the standards is given on its certificate at specific date and time. Its activity at the time of calibrating the detector, and consequently will not be recognized as originating from the specific IRN.

For some elements, mainly gold and tantalum, the radionuclides produced by the \((n,\gamma)\) reaction with the reactor neutrons have exceptionally high cross-sections (e.g. for \(^{198}\text{Au}\) the cross-section is \(2.5 \times 10^8\) b). Owing to the high cross-section and although their concentration is very limited, a radionuclei is formed by absorption of two neutrons (in two consecutive steps and not in one interaction) in the stable nuclide. For example, for gold, which has only one stable isotope, \(^{197}\text{Au}\), the process is illustrated by Equation (29):

\[
^{197}\text{Au} \longrightarrow^{2n}^{199}\text{Au}
\]

For \(^{198}\text{Au}\), the rate of formation is given by Equation (30):

\[
\frac{d[^{198}\text{Au}]}{dr} = \left[^{197}\text{Au}\right] \sigma_1 \phi - (\lambda_1 + \sigma_2 \phi) [^{198}\text{Au}]
\]

(30)

Equation (30) is the same as Equation (19) substituting \(\lambda\) for \(\alpha_1 = \lambda_1 + \sigma_2 \phi\). Hence the number of \(^{198}\text{Au}\) atoms at the end of irradiation is given by Equation (31):

\[
N_{^{198}\text{Au}}(\text{EOI}) = \frac{\sigma_1 \phi [^{197}\text{Au}]}{\lambda_1 + \sigma_2 \phi} [1 - e^{-(\lambda_1 + \sigma_2 \phi) t}]
\]

\[
= \frac{\sigma_1 \phi [^{197}\text{Au}]}{\alpha_1} [1 - e^{-\alpha_1 t}]
\]

(31)

For \(^{199}\text{Au}\), the rate of formation is given by Equation (32):

\[
\frac{d[^{199}\text{Au}]}{dr} = \sigma_2 \phi [^{198}\text{Au}] - \lambda_2 [^{199}\text{Au}]
\]

(32)

This is similar to the set of the differential Equations (15), differing in that the constants in the positive term in one equation differ from those in the negative term in the next one, as not all of the disappearance of \(R_i\) leads to \(R_{i+1}\); however the same method of Bateman can be used also here. The solution of Equation (32), substituting in it Equation (31), yields Equation (33):

\[
[^{199}\text{Au}] = \frac{\sigma_1 \sigma_2 \phi^2 [^{197}\text{Au}]^0}{\alpha_1 \lambda_2^2} \left(1 - \frac{\lambda_2 e^{-\alpha_1 t} - \alpha_1 e^{-\lambda_2 t}}{\lambda_2 - \alpha_1}\right)
\]

(33)

This equation neglects the disappearance of \(^{199}\text{Au}\) due to the absorption of neutrons. An equation which includes it was given by Heydorn,\(^{(14)}\) but its contribution is negligible for all fluxes used in activation analysis. The general treatment can be found in Friedlander et al.\(^{(3)}\) (p. 201).
3 THE SHAPE OF A γ SPECTRUM

In optical (absorption and emission) spectrometry we know that if a species has only one excited state its spectrum will appear as a single line without any background. This is due to the yes/no quantum characteristic of the energy transfer. The energy difference between the two states is either transferred or not transferred, but it cannot be transferred in parts. A photon of light in the infrared, visible or ultraviolet range can be absorbed totally or not at all, but it cannot lose only part of its energy. The situation is different for high-energy γ-rays. Low-energy X-rays interact with matter by the photoelectric process. In this process the γ-photon interacts with one electron of the material, losing all its energy to this electron. The transferred energy is higher than the binding energy of the electron, and thus the electron is ejected from the atom with kinetic energy equal to this difference \((\text{binding energy of the photon})\). However, since the range of high kinetic energy electrons is considerably shorter than that of γ-rays, the electrons will lose their kinetic energy inside the detector material and from the point of view of the detector the complete energy of the photon have been absorbed in it, resulting in the same energy absorbed for all photons (assuming that all photons are of the same energy). The situation is different for higher energy γ-rays. The cross-section (probability of reaction = rate constant) for the photoelectric process decreases with increasing energy of the photon more than that of the Compton scattering. For higher energy photons the main interaction with matter is via Compton scattering. In germanium the photoelectric effect is the dominant process for γ interaction up to about 200 keV, whereas from 200 keV upwards the Compton scattering becomes more important. It should be stressed that also below 200 keV the Compton scattering occurs but its contribution to the interaction of the photon with the germanium is less than that of the photoelectric process. Its contribution increases with the energy although its cross-section decreases with the energy, since it decreases less than that of the photoelectric process. In the Compton scattering the photon interacts with what might be called a free electron (mainly electrons from outer shells whereas the photoelectric process occurs with inner shell electrons, mainly from the innermost one, the K shell). The photon transmits only part of its energy. The energy that the electron receives is more than sufficient to eject it from the atom and it moves with the excess energy as kinetic energy, losing it by collisions in a very short distance. The photon retains part of its energy, by changing its frequency since \(E = \text{photon} \times \text{frequency} \), and scattered in a different direction. In the Compton process the energy of the original photon is shared between two particles (the ejected electron and the scattered photon), and consequently there is a continuous distribution of energies of the scattered photon. In order to conserve both energy and momentum, the γ-photon cannot lose all its energy (in the photoelectric effect the momentum conservation is compensated by the recoiling of the atom from which the electron was ejected, whereas in Compton scattering it is an interaction with a ‘free’ electron). The maximum energy that the photon can lose is given by Equation (34):

\[
E_\gamma \frac{1}{1 + m_0c^2/2E_\gamma}
\]

where \(E_\gamma\) is the energy of the initial photon and \(m_0\) is the electron rest mass; \(m_0c^2\) is the rest mass of an electron in energy units and it is equal to 0.511 MeV. The main difference between the photoelectric and Compton processes with respect to their responses in the detector material is that the electrons (in both processes) lose all their energy in the detector, owing to their short range, while the scattered photon might escape from the crystal without further interaction. In γ-ray spectrometry we are measuring the full-energy peak, called the photopeak, as this energy will be the only one to appear if the only interaction process is photoelectric absorption. The photopeak results either from the γ-photons losing all their energy by photoelectric absorption or from a Compton scattering process followed by photoelectric absorption of the scattered lower energy γ-photon in the detector (the photoelectric absorption can be after one scattering or several scatterings, all of them within the detector material). However, the scattered γ-photon from the Compton process (actually from the several consecutive Compton processes) might escape from the detector crystal, leaving in the detector less energy than the full energy peak. This escape of scattered photons not only reduces the photopeak, but its main disadvantage is the formation of a background for lower energy peaks, since part of the energy (those given to the electron) is absorbed in the detector and the detector sees them as counts of lower γ energy than the actual energy of the γ-photon emitted by the IRN. The scattered photons do not have discrete energy and can be between a minimum given by Equation (34) and a maximum given by the original energy of the photon (minus the small value of the binding energy of the photon, which is not completely a free electron). For one γ energy source the Compton scattering produces a continuum background ranging from zero up to a maximum, called the Compton edge, given by Equation (35). This results from the fact that the minimum energy that the scattered photon can have is not zero but rather is given by Equation (35):

\[
E_{\text{minimum of scattered }} = E_\gamma \left(1 - \frac{E_\gamma}{1 + m_0c^2/2E_\gamma}\right) = \frac{E_\gamma m_0c^2}{2E_\gamma + m_0c^2}
\]
For $E_\gamma \gg m_0 c^2$, $E_{\text{minimum}}$ approaches a value of $m_0 c^2/2$, i.e. 256 keV. Thus, for high-energy $\gamma$ the Compton edge will be separated from the photopeak by about 256 keV. For a one-energy source the range between the photopeak and the Compton edge is almost free of counts. However, most real samples have many IRNs having different $\gamma$ energies and the Compton continuum stretches from zero up to the Compton edge of the highest $\gamma$ energy.

If the energy of the measured photon is $>1.022$ MeV, a third process can also be operative in the interaction of the photon with the detector – a process called pair production. In this process, the photon energy is transformed, under the influence of the field of a nucleus, into matter in the form of an electron–positron pair (transformation of energy into a matter–antimatter pair). Since the rest mass of each electron or positron is $<1.022$ MeV, the threshold of this reaction is $1.022$ MeV to conserve energy. Although the threshold energy is $1.022$ MeV, the cross-section for pair production is very low, for the energy range of $<1.5–1.6$ MeV, and can be ignored. In this process of pair production, the excess energy is shared between the kinetic energies of the two photons. If one of the $511$-keV photons deposits all its energy in the detector, while the other one totally escapes from the detector, the energy absorbed in the detector will be $511$ keV less than the full energy peak. With $\gamma$-photons of above $1.6$ MeV we usually see also this peak of $E_\gamma = 511$ keV, where $E_\gamma$ is the photopeak energy. This peak is called single-escape (SE) peak, due to one $511$-keV photon escaping from the detector. Another peak in the spectrum is the double-escape (DE) peak, rising from the two $511$-keV photons escaping from the detector. The energy of this peak is $E_\gamma = 1.022$ MeV. When analyzing a $\gamma$-ray spectrum to find the radionuclides in the analyzed spectrum, every time we find a peak with energy $E_\gamma > 1.6$ MeV, which we know belongs to some radionuclide, we have to remember that in the list of the found peaks there are some which do not belong to other radionuclides but are either SE or DE peaks. We saw that $^{28}$Al has a $\gamma$ energy of $1.778$ MeV. Hence we expect to see in the $^{28}$Al $\gamma$-ray spectrum peaks of $1.778$ MeV, $1.269$ MeV (SE = 1.778 – 0.511) and $0.758$ MeV (DE peak). $^{24}$Na has two $\gamma$ lines of $2.75$ and $1.39$ MeV. We expect to have four lines in the $\gamma$-ray spectrum, $2.75$ MeV, $2.24$ MeV (SE), $1.73$ MeV (DE) and $1.39$ MeV. Although $1.39$ MeV is above the threshold of $1.022$ MeV for pair production, its cross-section for this process is low and pair production contributes very little to the interaction of the $1.39$-MeV photon with the detector. Hence in most cases we will not see the SE and DE peaks of this photon.

Figure 1 shows the measured $\gamma$-ray spectrum of $^{24}$Na. The ratio of escape peaks to the photopeak depends on the detector size (influencing the probability of the $\gamma$ escape) and on the energy of the $\gamma$-photon (affecting the chance that the photon will interact by pair production). In order to know whether a peak is a photopeak or SE or DE, it is preferable to start the analysis of the spectrum from the highest energy peak. For each peak we can remove from the list of peaks its SE and DE peaks.

An important artefact in many $\gamma$-ray spectra is the sum peak, a peak which is due to the summation of two $\gamma$-photons. If two photons are interacting with the detector, and the time between them reaching the crystal is smaller than a time characteristic of the detector, the detector treats both of them as a single photon and the energy deposited is the sum of the energies of the two photons. The two photons can be due to different radionuclides.

\begin{figure}
\centering
\includegraphics[width=0.5\textwidth]{figure1.png}
\caption{\textbf{$\gamma$-Ray spectrum of $^{24}$Na radioisotope taken with an HPGe detector.} (1) Photopeak of 2754 keV; (2) SE peak of 2243 keV (2754–511 keV); (3) DE peak at 1732 keV (2754–1022 keV); (4) photopeak at 1369 keV; (5) 511-keV positron annihilation.}
\end{figure}
or to the same radionuclide which has more than one $\gamma$ line. In the case of different radionuclides the sum peak is refer to ‘pile-up’ and can be reduced (relative to the photopeaks) by removing the measured sample further from the detector or by analyzing a smaller sample. A lower rate of counting increases the average time between two photons reaching the detector, thus decreasing the chances of pile-up. In the spectrum of only one $\gamma$ line there is also a peak with energy given by Equation (35). This peak is due to 180° backscattering from external sources, mainly the shielding of the detector, of the original photon. The backscattered Compton photon reacts with the detector, giving a peak of its full energy. For a source with various $\gamma$-ray energies, this backscatter peak can range from 70 to 256 keV, thus adding to the Compton continuum rather than forming a distinct peak.

The Compton background is an intrinsic background due to the physical characteristics of the detector and the interaction of radiation with matter. Another source of background is external, due either to radioactive sources other than our sample or to cosmic radiation. This external background can be minimized by the use of shielding, done mainly with lead owing to its high $Z$ and mainly its high density. Usually the detector is located inside a lead ‘castle’. Lead shielding configurations suitable for a germanium detector are available commercially, usually in the form of a hollow cylinder with a sliding lid or revolving door for access.

In many cases where the Compton continuum interferes with the measurements of mainly small peaks, it can be reduced by the use of the Compton suppression method. In this method, the germanium detector is located inside an annular scintillation detector or inside a ring of scintillation detectors. Many of the scattered Compton $\gamma$-rays which escape from the germanium detector (in the case of the Compton continuum) deposit some energy in the surrounding detectors, whereas those photons which lose all their energy in the germanium detector do not cause any signal in the scintillation detector(s). The system is operated in the anticoincidence mode, i.e. the multichannel analyzer (MCA) is recording only the events which occur only in the germanium detectors. If within a fixed time the pulse in the germanium detector is followed with a pulse in the scintillation detector (indicating that the germanium pulse is in the Compton continuum and not part of a photopeak), this event is discarded. The scintillation detector(s) are usually NaI(Tl), although in some systems it is a crystal of bismuth germanate (BGO) ($\text{Bi}_2\text{Ge}_3\text{O}_{12}$) owing to its higher efficiency for absorption of $\gamma$-rays (since it has a high-$Z$ element). However, BGO crystals are more expensive and are not used in most systems. A schematic diagram of a Compton suppression system is given in Figure 2.

4 NEUTRON SOURCES

Three main sources of neutrons are available: (1) research nuclear reactors (nuclear reactors used as neutron sources), (2) ion and electron accelerators including neutron generators and (3) radioactive sources.

Research nuclear reactors have the highest neutron fluxes, but are limited concerning their price and availability. Consequently, nuclear reactors will be used for INAA of very minute amounts, which is the main subject of this article. Research nuclear reactors are usually large devices in which fissionable material, almost exclusively $^{235}\text{U}$, is fissioned into two nuclides with simultaneous emission of neutrons which induce further fissions in a chain reaction. The fission-produced neutrons are very energetic. The cross-section for neutron-induced fission of fissionable nuclides increases with decreasing energy of the neutrons, and in order to increase the neutron activity, moderators which slow the neutrons are added to the reactor. To reflect back some of the neutrons which leak from the reactor core, reflectors are used. The fission process releases large amounts of energy, mainly due to the stopping of the two recoiling fissioned particles, and the system is cooled by a coolant (either liquid or gas). Nuclear reactors are categorized according to their fuel, moderator, coolant, reflector and configuration.

Almost all research nuclear reactors (neutron sources) are heterogeneous reactors in which the fuel is in the form of rods. The fuel is enriched $^{235}\text{U}$ (natural uranium has only 0.7% of $^{235}\text{U}$, the fissile material). Most research reactors have 93–99% $^{235}\text{U}$. Many of the reactors have rods which are U–Al alloys, but some

---

Figure 2 Schematic diagram of anticoincidence Compton suppression $\gamma$-spectrometer. (1) HPGe detector with liquid nitrogen cooling; (2) NaI(Tl) detectors with photomultipliers.
of the newer designs (mainly those converted to 20% $^{235}$U) are of the uranium silicide type. TRIGA reactors operate with uranium–zirconium hydride fuel, which, owing to their large negative temperature coefficient of reactivity, allow the operation of the reactor in pulses. In the light water reactor (LWR), ordinary water ($H_2O$) is used both as a moderator and as a coolant. The reflector is mainly graphite but there are also Be and $H_2$ reflected reactors. The construction is either pool type or tank-in-pool type. Owing to the relative high cross-section for capturing thermal neutrons by H atoms and therefore the relatively small amount of moderator, the flux of neutrons in LWRs always contains a large fraction of fast and epithermal neutrons. The available powers are in the range 10–5000 kW with neutron fluxes of $5 \times 10^{10} - 1.5 \times 10^{14} \text{n cm}^{-2} \text{s}^{-1}$. Many reactors are unique in their design, but there are some commercial types which are more common, e.g. the American TRIGA and the Canadian Slowpoke. The TRIGA reactor is a popular multipurpose research reactor. About 50 of them are operating with power levels of 18 kW–3 MW fluxes of $7 \times 10^{11} - 3 \times 10^{13} \text{n cm}^{-2} \text{s}^{-1}$. The most common types are those of 250 kW and 1 MW. They are of the pool type, graphite reflected with uranium–zirconium hydride fuel with $^{235}$U enrichment of 10–70%. The Slowpoke reactor is a low-power (20 kW) reactor designed specifically as a teaching aid. The fluxes of up to 5

4.1 Sample Introduction

The way of introducing a sample into the neutron flux depends on the physical structure of the reactor. It is essential that the introduction of the sample will not affect the operation of the reactor. The irradiation site may be within the reactor core or outside in the moderator/reflector region. If the reactor is an open-pool type with access from above, vertical tubes or ropes can be installed to lower the samples down inside the core or close to the side. The samples are closed in sealed ampules in order not to be in contact with the water surrounding the core. The ampules are usually made of aluminum owing to its corrosion resistance and short-lived activation products. For short irradiations a polyethylene capsule can also be used. The manual loading of samples is neither quick nor reproducible in time when short irradiations are performed. In order to have quick and reproducible sample introduction, mechanical systems are used. Two types of mechanical systems are used: chain-driven racks and pneumatic devices. The latter is the most common, owing to the shorter loading and unloading time and less maintenance and failures of operation. In the pneumatic device, the sample is pushed along a tube with pressurized gas (air or nitrogen). The transfer time depends on the pressure and the distance transferred. In many systems the transit time is 1 s or less. The pneumatic device can be automated very easily. Figure 3 depicts schematically the pneumatic system.

With closed-tank reactors, the irradiation is done either by a pneumatic device or with neutron beams.

5 INSTRUMENTAL NEUTRON ACTIVATION ANALYSIS

5.1 Techniques

INAA is one of the simplest techniques for trace element analysis. Samples are inserted into polyethylene or polypropylene cans for short irradiation or into a quartz vial which is inserted in an aluminum can for long irradiation. PVC cans or glass vials cannot be used, since they will be become very radioactive owing to the formation of $^{38}$Cl or $^{24}$Na, respectively. For a short irradiation time each sample is ‘sent’ alone
to the reactor by means of a pneumatically operated tube—the rabbit system. For long irradiation times, many samples can be lowered into the reactor and left there for the required time. After the samples have been removed from the reactors, they are counted (this means taking a γ-ray spectrum) immediately or the γ-ray spectrum is taken after some ‘cooling’ (decay) time, to reduce the high radioactivity level due to short-lived radionuclides. Before counting, the vials are washed to remove surface contaminants. In some cases the samples are counted inside the vial, whereas in others the samples are taken out of the vial before the measurement, owing to interferences from trace elements in the vial.

5.2 Calculation

In general, the first calculation step consists of peak identification, i.e. identification of which peaks are photopeaks (discarding SE, DE and sum peaks) and identification of the radioactive species which are producing them. There are tables of γ-ray energies listed in order of increasing energies for ease of identification.\(^{9-13}\) Some tables give the energies of all known radionuclides whereas others give them only for radionuclides which can be formed in one form of nuclear activation, e.g. in a nuclear reactor. For better identification the tables give the half-life of this radionuclide, its probability of formation and other γ lines of the same radionuclide. Thus, if we find one γ peak of some radionuclide, but not its other line/lines, it means a wrong identification. The different lines also have to be checked to be in the reported ratios, taking into account the relative intensities of the γ lines and the efficiency of the detector at those energies. Nowadays most MCAs are computer (PC)-based and have in their data a nuclide library. However, most libraries check only for the energy of the photopeak with a preset tolerance of 1–2 keV. Some commercial computer programs check also for the presence (in the right ratios) of the other lines of the same radionuclide. Most programs do not treat the identification through half-lives. It should be remembered that SE and DE energies are not listed in most libraries of 1–2 keV. Some commercial computer programs check also for the presence (in the right ratios) of the other lines of the same radionuclide. Most programs do not treat the identification through half-lives. It should be remembered that SE and DE energies are not listed in most libraries and this can lead to misidentifications. Figure 4 gives an example of γ-ray spectra measured from an activated sample.

The second step in the calculation is calculation of the net counts under the peak (plotted as number of counts in each channel per channel number). Various methods exist for the evaluation of the net peak ‘area’ (really it is the net peak counts). The simpler methods define the channels which belong to this peak and sum all the counts in that peak [Equation 36]:

$$\text{total} = \sum_{i=L}^{u} C_i$$  (36)

where \(C_i\) is the counts in channel number \(i\), and \(L\) and \(u\) are the lower and upper channels belonging to the peak. However, this total count value contains also the background (Compton and external), which should be subtracted. The background is estimated by taking the average number of counts in 3–5 channels on both sides of the peak, multiplying by the number of channels in the peak [Equation 37]:

$$\text{background} = \frac{u - L + 1}{2 \times 3} \left( \sum_{i=L-3}^{L-1} C_i + \sum_{i=u+1}^{u+3} C_i \right)$$  (37)

The value of 3 in this equation can be increased or decreased, but it is about the optimum value; lower numbers will increase the statistical error in the evaluation of the background, and larger numbers will increase the possibility that the following channels belong already to other peaks. The radioactive decay is not an absolute process but rather of a statistical nature, and consequently the larger the number of counts the more accurate is the result. The standard deviation of each decay count (as long as the counting time is small compared with the half-life of the measured radionuclide) is equal to the square root of the number of counts. The number of net counts is given by Equation (38):

$$N = \text{net counts} = T - B$$  (38)

The standard deviation of the net counts, \(\sigma_N\), and the relative standard deviation, \(\% \sigma_N\), are given by
Equations (39) and (40):

\[ \sigma_N = \sqrt{T + B} = \sqrt{N + 2B} \]  
\[ \%\sigma_N = \frac{100(\sqrt{T + B})}{N} = \frac{100(\sqrt{N + 2B})}{N} \]

It should be kept in mind that the rate of counting is limited both by the rate of the process in the detector (which causes ‘pile-up’ or a sum peak in the case of high rates of counts) and by the rate of the sorting-out of pulses by the MCA and the electronic system. During the ‘busy’ period of the electronic system, they cannot acquire another signal, so that each signal reaching the system during its ‘busy’ period will be discarded. This ‘busy’ period is called the dead time and the actual measurement time (live time) is smaller than the real time (measured by the clock). Most MCA systems contain a device for correction of the dead time. However, these devices are accurate only up to about 10% dead time. It is usually recommended not to measure with dead times.

The ‘busy’ period of the electronic system is limited both by the rate of the process in the detector which surrounds the source from all directions, i.e. a particle generator with a known rate at which its pulses are introduced to the same electronic system (the height of the pulse is chosen in a range were there are no γ signals), calculating the live time from the ratio of the measured to expected counts from the pulse generator. Instead of using a pulse generator, the longer lived radionuclide can be measured after partial decay or preferably at larger distance.

### 5.2.1 Calibration and Calculation

The amount of a nuclide in a sample can be calculated from the counts of the radionuclide produced from its neutron activation by the use of Equation (28) if the physical constants \( \sigma, f, I_e, \phi \) and \( \lambda \) are known and the geometry factor \( \varepsilon \) is measured by using calibrated radioactive standards, which can be bought commercially. These standards are calibrated in a 4π detector, i.e. a detector which surrounds the source from all directions such that any β-particle or photon interacts with the detector. The geometry factor \( \varepsilon \) depends on the distance of the source from the detector and the energy of the γ line. For a fixed distance, \( \varepsilon \) is a maximum type function of the energy, the maximum being at 100~150 keV. For higher energies than the maximum, \( \log \varepsilon \) is approximately a linear function of \( \log(\text{energy}) \), although for more accurate interpolation a quadratic dependence of \( \log \varepsilon \) on \( \log(\text{energy}) \) is used. Standard sources often used for calibration are \(^{241}\)Am (60 keV), \(^{131}\)Ba (81, 302, 356 and 383 keV), \(^{137}\)Cs (661 keV), \(^{60}\)Co (1773 and 1332 keV), \(^{22}\)Na (1275 keV) and \(^{88}\)Y (898 and 1836 keV). These standard radioactive sources are used also for the calibration of the number of channels vs. the appropriate γ energy. The standard radioactive sources are supplied with a certificate, certifying their activity at a fixed date. The activity is given either in microcuries [1 µCi = 3.7 x 10^4 dps (disintegrations per second)] or in kilobecquerels (1 kBq = 10^3 Bq, 1 Bq = 1 dps, 1 µCi = 37 kBq). The activity of the source at the measurement is calculated by the use of Equation (41) which is derived from Equation (2):

\[ A(t) = A_0 \exp(-\lambda t) \]

where \( A(t) \) is the activity at the measurement time, \( A_0 \) is the certified activity and \( t \) is the time elapsed from the date of certification to the measurement.

The parameters \( f, I_e \) and \( \lambda \) are tabulated and known very accurately. However, \( \sigma \) is a function of the energy of the neutrons and the real term in Equation (28) should not be \( \sigma \phi \) but rather the integral \[ \int_0^\infty \sigma(E) n(E) \text{d}E, \] where \( n(E) \) is the energy – flux density or the flux distribution function (number of neutrons per second per square centimeter for which their energy is in the range \( E \) to \( E + \text{d}E \)), \( \phi = \int_0^\infty n(E) \text{d}E \). These functions \( n(E) \) and \( \sigma(E) \) are not always known and sometimes they change with time and with location in the reactor. In order to overcome this problem, the use of comparators has been applied to calculate the results of neutron activation analysis (NAA). A comparator is a standard which contains a known amount of the element to be determined in the sample. If the sample (denoted by subscript s) and the comparator (denoted by subscript c) are irradiated simultaneously and counted under the same conditions, then Equation (26) gives Equation (42):

\[ m_s = m_c \frac{C_s D_c M_c}{C_c D_s M_s} \]
are determined simultaneously (more accurately, by three irradiations for different periods of times followed by 5–6 countings at different times after the irradiations for various periods of times).\(^\text{18–23}\) For these multielement determinations it is difficult to prepare comparators for all the elements, and further it become impractical owing to the large amount of space required for all the comparators. Thus for multielement analysis either multielemental comparators have to be used, or one or two element comparators are used for calculation of other elements. Some multielement standards (comparators) of different types (geological, biological, etc.) have been prepared either by groups of scientists or by governmental or international organizations. However, such a standard [standard reference material (SRM)] is not recommended as a primary standard owing to some large uncertainties in some elements and problems with homogeneity of small samples (of the SRMs) used in INAA.

The use of one or two elements as comparators for all elements has become more widely used in recent years. The advantage of using two elements or one element with two isotopes which are activated is that the use of two activated nuclides, if chosen well, can give more information on the energy distribution of the neutron flux in the reactor.\(^\text{24–26}\) The most popular method is the so-called \(k_0\) method, in which \(k_0\) values were determined for most of the elements according to Equation (43):

\[
k_0 = \frac{B_c}{B_s}
\]  

(43)

where [Equation 44]

\[
B = \frac{C}{f \sigma_b}
\]

(44)

and the subscripts \(c\) and \(s\) stand for comparator and sample/element, respectively, and \(\sigma_b\) is the cross-section for reaction with thermal neutrons. The most popular comparator is \(\text{Zr}\), which has two activatable isotopes, used to monitor the thermal and epithermal flux simultaneously. The calculation of the amount of the different elements involve both the thermal and epithermal neutrons.

### 5.3 Nuclear Interferences

There are two main kinds of interferences in the calculation of trace element concentration by INAA. The first is the formation of the same radionuclide from two different elements. This would be almost impossible if all neutrons were thermal neutrons since then the only possible reaction is \((n,\gamma)\). However, all reactors have some higher energy neutrons, which can induce other reactions. Examples of this case are the determination of Mg in the presence of Al, Cr in the presence of Si or P. Mg can be determined only through its less abundant isotope \(^{28}\text{Mg}\) which is formed by the \((\text{n},\gamma)\) reaction. The cross-section for this reaction is rather low, making this measurement not very sensitive. It suffers interference since \(^{27}\text{Mg}\) can be formed from nonthermal neutrons reacting with Al in an \((\text{n},\text{p})\) reaction, \(^{27}\text{Al}(\text{n},\text{p})^{27}\text{Mg}\). Similarly, the determination of chromium by the \(^{59}\text{Cr}(\text{n},\gamma)^{51}\text{Cr}\) reaction suffers interference from the nonthermal neutron reaction \(^{54}\text{Fe}(\text{n},\alpha)^{51}\text{Cr}\). \text{Al} is determined by the \(^{28}\text{Al},^{27}\text{Al}(\text{n},\gamma)^{28}\text{Al}\) reaction, which can be produced also by the reactions \(^{31}\text{P}(\text{n},\alpha)^{28}\text{Al}\) and \(^{28}\text{Si}(\text{n},\text{p})^{28}\text{Al}\). In a flesh sample it was found that the contribution of \(\text{Pt}\) to \(^{28}\text{Al}\) is more than \(10\) times that of the \(^{28}\text{Al}\) from \(\text{Al}\), in most reactors.\(^\text{27–31}\)

Even for only thermal neutrons in few cases a specific IRN can be formed from two elements, in cases where the IRN can be formed also by consecutive reaction with two neutrons. \text{Pt} has several IRNs but all of them except one are short-lived and suffer from interferences from the major element background. Hence, for minute amounts of \(\text{Pt}\) it is determined by \(^{199}\text{Au}\) formed in the process shown by Equation (45):

\[
^{198}\text{Pt} \rightarrow^{199}\text{Pt} \rightarrow^{199}\text{Au}(3.139\text{ d}, 158.3\text{ keV/line})
\]

However \(^{199}\text{Au}\) is formed also by a two-neutron reaction with \(^{197}\text{Au}\), since \(^{198}\text{Au}\) has a very high cross-section for neutron capture \((2.65 \times 10^8\text{ b})\)\(^\text{32,33}\) [Equation 46]:

\[
^{197}\text{Au} \rightarrow^{198}\text{Au} \rightarrow^{199}\text{Au}
\]

Another kind of interference is from two radionuclides having very close \(\gamma\) lines. An example of this kind of interference is the \(846.8\)-keV line of \(^{56}\text{Mn}\) and the \(843.8\)-keV line of \(^{27}\text{Mg}\). The activity of the two lines is comparable but this is impossible for low-resolution germanium detectors or when one activity is much higher. If they cannot be separated by the spectrometer there are two ways to overcome this interference:

1. Since the half-life of \(^{56}\text{Mn}\) (2.56 h) is longer than that of \(^{27}\text{Mg}\) (9.45 min), decay of 2 h will leave practically only \(^{56}\text{Mn}\) (the activity of \(^{27}\text{Mg}\) will decrease by a factor of 6647 whereas the \(^{56}\text{Mn}\) activity will be decreased by a factor of less than two). Thus measurements of the sample after the irradiation and after decay of 2–3 h will give the activities of both \(^{56}\text{Mn}\) (from the delayed measurement) and \(^{27}\text{Mg}\) (by subtracting the corrected activity of \(^{56}\text{Mn}\) from the first measurement).

2. The activities of both radionuclides can be calculated using the fact that \(^{27}\text{Mg}\) also has another \(\gamma\) line at 1014 keV. The ratio of the activities of the two lines
NUCLEAR METHODS

can be measured in a pure sample of Mg, and thus the 843.8-keV activity of $^{27}$Mg can be calculated from the 1014-keV activity. Subtracting this activity from the combined (843.8 + 846.8)-keV peak yields the activity of $^{56}$Mn 846.8-keV peak.

5.4 A Test Case: Instrumental Neutron Activation Analysis of Trace Elements in Silicon

Silicon has three naturally stable isotopes, $^{28}$Si (92.21%), $^{29}$Si (4.70%) and $^{30}$Si (3.09%). Thus only $^{30}$Si produces a radionuclide by the usual ($n,\gamma$) reaction of thermal neutrons. $^{31}$Si produced by the $^{30}$Si($n,\gamma$)$^{31}$Si reaction has a 2.62-h half-life and very few $\gamma$-rays, with an intensity of only 0.07% (1.26 MeV). Considering the low abundance, the relatively low cross-section (0.28 b) and mainly the low intensity of the $\gamma$-rays, $^{31}$Si does not present a large problem in instrumental analysis by $\gamma$-ray spectrometry.

However, owing to the presence of fast and epithermal neutrons in the reactor, the main activity induced in silicon is due to $^{28}$Al, $^{29}$Al and $^{27}$Mg formed by the reactions $^{28}$Si($n,p$)$^{28}$Al, $^{29}$Si($n,p$)$^{29}$Al and $^{30}$Si($n,\alpha$)$^{27}$Mg. As the half-lives of these radionuclides are short (2.3, 6.6 and 9.5 min, respectively), INAA is possible for radionuclides with half-lives longer than 1–2 h. In any case, the activity induced in nuclides with shorter half-lives is usually not sufficient to measure the required purity for electronic-grade semiconductors, owing to the small amount of radioactive atoms which can be formed until reaching saturation. As there is no background from the Si matrix after about a day or two and since the concentrations of the trace elements are low, the ways to increase the sensitivity (decrease the lower limit of detection) are to irradiate with a larger total number of neutrons (higher flux, longer irradiation times or both). In the high flux reactor (HFR) at Petten, The

* Verheijke et al.\(^{35}\) irradiated wafers of 15 mm diameter and 0.5 mm thickness (20.6 g) with a flux of $4 \times 10^{13}$ n cm$^{-2}$ s$^{-1}$ for 72–96 h and counted for 6–8 h; Lindstrom\(^{36}\) irradiated samples of 100 mg for up to 6 h at $5 \times 10^{13}$ n cm$^{-2}$ s$^{-1}$; Revel et al.\(^{37,38}\) used 1 g of Si and irradiated for 72 h at $2.3 \times 10^{14}$ n cm$^{-2}$ s$^{-1}$; Fujingawa and Kudo\(^{39}\) irradiated 5–10-g samples for 11 d at $2 \times 10^{13}$ n cm$^{-2}$ s$^{-1}$.
Netherlands, a special irradiation facility was constructed for irradiation of silicon samples from Philips, in which silicon wafers of up to 15 cm in diameter can be irradiated with $4 \times 10^{13}$ thermal n cm$^{-2}$ s$^{-1}$ and the irradiation is done for 72–96 h. They also used large Ge(Li) detectors (100–150 cm$^3$) and counted for 8–16 h, and obtained the lowest detection limits. Table 1 summarizes some of the limits of detection given in the literature for an Si matrix. For some elements, e.g. Cl and Mn, shorter irradiations were used, between 0.5 and 2.0 h. A special correction has to be done in the case of the determination of Na owing to the reaction $^{28}\text{Si}(n,p)^{24}\text{Na}$, as was shown by Niese by irradiating very pure Si in a reactor core with and without a Cd cover to absorb the thermal neutrons. The contribution of the $^{28}\text{Si}(n,p)^{24}\text{Na}$ reaction to $^{24}\text{Na}$ in a silicon matrix depends on the spectrum of the neutrons in the reactor core, as very high energy is required for this reaction and the Q value exceeds that of a 14-MeV neutron generator. Niese found that the contribution of the $^{28}\text{Si}(n,p)^{24}\text{Na}$ reaction is equal to 0.7 ppb. For the HFR at Petten, The Netherlands, the contribution is 0.55 or 0.6 ppb. Revel et al. found this contribution of the $^{28}\text{Si}(n,p)^{24}\text{Na}$ reaction to be <0.4 ppb. Haas et al. warned against the common use of wrapping the sample for irradiation in Al foil, as they showed that there is recoil of $^{24}\text{Na}$ from the Al wrapping to the sample, due to the high recoil energy from the $^{27}\text{Al}(n,\alpha)^{24}\text{Na}$ reaction. In many other uses it is not important, but owing to the very low concentration of Na in pure Si, this contribution might be considerable.

Several important elements cannot be determined in this method, including mainly the light elements H, Li, Be, B, C, N, O and F as they do not form radioisotopes or they are too short lived. Phosphorus cannot be determined in this way owing to a lack of $\gamma$ emission from the only produced $^{32}\text{P}$; however, $^{32}\text{P} \beta$-rays can be determined destructively by the extraction of the phosphomolybdic complex in the presence of hold-back carriers of Ta and Au. The chemical yield of the extraction was found to be 83.8 ± 4% and the decontamination factors were 79–6500 for the different elements studied. The limit of detection was found to be $3 \times 10^{-11}$ g. They carried out their study for phosphorus-doped silicon and Alfassi and Yang showed that for this case, there is no need for chemical separation and 10–20 d of cooling are sufficient to ensure that the only $\beta$ emitter is $^{32}\text{P}$ (with an accuracy of 1–2%, which is much better than the reproducibility of the extraction yield). The limit of detection should be about the same, as both methods use liquid scintillation counting for the measurement of the $\beta$ activity, although Alfassi and Yang used a discriminator which reduces the detection limit by a factor of two.

5.5 An Example of Interference Removal in Instrumental Neutron Activation Analysis:
Determination of Platinum in Aerosols

Pt is emitted into the air by corrosion of the catalytic converters used in cars to reduce the emission of CO, NO$_x$ and unburned hydrocarbons. In order to determine the concentration of Pt in the air, a high-volume air-pump air through a filter and the amount deposited on the filter (together with the aerosols) is determined. Pt can be determined via several radionuclides. Pt suffers from very low abundance (0.01%) of the parent stable nuclide, $^{190}\text{Pt}$, $^{197}\text{Pt}$ and $^{199}\text{Pt}$ suffer from relatively short half-lives (18.3 h and 30.8 min). If a measurement is made shortly after the irradiation, these IRNs could not be observed owing to the large amounts of Compton-scattered photons from the major elements Na, Cl and Br. Thus Pt can be determined in minute amounts only via $^{199}\text{Au}$ [3.14 d, 158.4 keV (36.9%)], which is formed by the sequence of reactions in Equation (47):

$$^{198}\text{Pt}(7.2\%) \rightarrow^{199}\text{Pt} \rightarrow^{199}\text{Au}$$  \hspace{1cm} (47)

$^{199}\text{Au}$ suffers from the two kinds of interferences mentioned earlier: (1) it can be formed also from other elements besides Pt and (2) another radionuclide formed from other elements have a very close $\gamma$ line. In the following paragraphs we will show how these interferences can be overcome.

1. $^{199}\text{Au}$ can be formed also from the successive absorption of two neutrons by $^{197}\text{Au}$ owing to the very high cross-section for the $(n,\gamma)$ reaction of $^{198}\text{Au}$ (26 500 b) and the high cross-section for the $(n,\gamma)$ reaction of $^{197}\text{Au}$ (98.7 b) [Equation 48]:

$$^{197}\text{Au} \rightarrow^{198}\text{Au} \rightarrow^{199}\text{Au}$$  \hspace{1cm} (48)

Since $^{198}\text{Au}$ is a radionuclide with a close half-life to $^{199}\text{Au}$ (2.69 d), it can be measured simultaneously with $^{199}\text{Au}$, and can be used to calculate the concentration of Au in the sample and hence to calculate the contribution of Au to the measured peak of $^{199}\text{Au}$. Subtracting this contribution, we obtain the counts of $^{199}\text{Au}$ formed from $^{198}\text{Pt}$ and hence the concentration of Pt.

2. Another problem is the very close $\gamma$ lines of $^{199}\text{Au}$ (158.4 keV) and $^{47}\text{Ca}$ (159.3 keV). If similar counts are obtained for the two radionuclides, the $\gamma$ spectrum shows clearly two distinct peaks, although the lower one (158.4 keV) does not go to zero, and hence there is lower accuracy in the calculation of the area under each peak (i.e. the counts due to each radionuclide). The situation is worse when the number of counts...
of one of the radionuclides is considerably higher (ratio > 4), in which case the spectrum does not show two distinct peaks but one peak with a shoulder, more or less visible. In order to separate this composite peak into its two contributions, two methods can be used. An important remark concerning this measurement is not to use a computer convolution program to calculate the area of this peak, as it will be programmed with a fitting function which is characteristic for a pure photopeak. In this case it is better to calculate the area by a simple integration of the counts under the peak, subtracting a trapezoid for the background correction. The two methods for separation of the contributions are based on (i) the different temporal behaviors of the two contributions and (ii) another y line which allows the calculation of the contribution of one radionuclide to the mixed 158.4–159.3 keV peak, facilitating the calculation of the contribution of the other one by subtraction.

(a) Temporal separation: although $^{199}$Au and $^{47}$Sc have close half-lives which usually will not allow the temporal separation of their contributions, their parents [as none of them is produced directly from the (n,$\gamma$) reaction and are products of $\beta$ decay of the (n,$\gamma$) products] have considerably different half-lives and hence the two contributions can be separated by measuring twice and solving the two equations (obtained by writing equations for the expected counts, writing x and y for the masses of Pt and Ca) with the two unknowns $m_{Pt}$ and $m_{Ca}$ (or x and y, $x = m_{Pt}$ and $y = m_{Ca}$) [Equations 49 and 50]:

\[
198\text{Pt} \rightarrow 199\text{Pt} \rightarrow 199\text{Au} \quad (49) \\
46\text{Ca} \rightarrow 47\text{Ca} \rightarrow 47\text{Sc} \quad (50)
\]

The disadvantage of this method is the need to make two measurements, hence the counting time required is more than doubled, since due to the delay between the two measurements the counting time of the second one must be longer than the first one in order to obtain the same statistical accuracy.

(b) $^{47}$Sc does not have a $\gamma$ peak without interference to calculate its contribution to the composite peak; however, its parent $^{47}$Ca has a good $\gamma$ line at 1297 keV without interference and this $\gamma$ line can be used to measure the concentration of Ca and consequently its contribution via $^{47}$Sc to the 158–159-keV peak.

The above contributory interferences are the only ones in a well-moderated nuclear reactor (heavy water moderated), while in most research reactors (light water moderated) the high-energy neutron flux will lead to additional interferences by the $^{47}$Ti(n,p)$^{47}$Sc and $^{199}$Hg(n,p)$^{199}$Au reactions. These interferences can be removed by additional irradiation inside a box made of B or Cd, which are thermal neutron absorbers, as explained in sections 5.6 and 5.7. However, this correction is not mandatory in most cases. The $^{199}$Hg(n,p)$^{199}$Au reaction can be neglected as the cross-section is lower than for (n,$\gamma$) and the fast flux is smaller than the thermal flux and the Hg concentration is low. The $^{47}$Ti(n,p)$^{47}$Sc reaction can be a greater problem owing to the higher concentration of the more abundant Ti. However, since Ti has several isotopes, the measurement of $^{48}$Sc, which can be formed only by the $^{48}$Ti(n,p)$^{48}$Sc reaction, can be used to calculate the contribution of the $^{47}$Ti(n,p)$^{47}$Sc reaction.

5.6 Epithermal Instrumental Neutron Activation Analysis

In the usual INAA, the whole reactor neutron energy spectrum is used. However, in some cases, the use of part of the neutron spectrum is preferable; these systems are characterized by large differences in the activation cross-sections for the desired and the interfering nuclides in the various parts of the energy spectrum. The required trace elements are activated with part of the neutron spectrum while the interfering major elements are activated more strongly with the other parts of the spectrum, and thus we prefer to avoid this second part.

The neutron energy spectrum in a nuclear reactor is usually divided, for convenience, into three portions, and their relative abundances are dependent on the reactor structure. The most abundant fraction is the one of thermal neutrons, i.e. those neutrons which are in thermal equilibrium with the moderator atoms. Their most expected energy is equal to $kT$ (where $k$ is Boltzmann’s constant and $T$ is the neutron temperature), which at room temperature is equal to about 0.025 eV. The neutrons with energy above that of the thermal neutrons are divided into fast neutrons, those which are directly from fission and have not been moderated at all with energy mainly above 1 MeV, and epithermal neutrons, i.e. partly moderated and having energy between tenths of an electronvolt and 1 MeV. When the whole reactor neutron energy spectrum is used for activation, the main contribution is from the thermal neutrons, also owing to their usually higher cross-section [(n,$\gamma$) reactions].

A special case where advantage can be taken of the epithermal and fast neutrons is the case where the required trace elements are activated more strongly...
relative to the major elements by the epithermal or fast neutrons. Most major elements in geology and biology follow the \(1/\nu\) cross-section rule (their activation cross-section is inversely proportional to the square root of the neutron energy) throughout the whole energy spectrum. On the other hand, many of the less abundant elements have, in addition to their thermal activation, large activation cross-section resonances in the epithermal energy region and consequently can be activated preferentially in this region. Similarly, several of the less common elements can be activated by other neutron reactions besides the common \(n,\gamma\) reaction. These \((n,p)\) and \((n,\alpha)\) reactions require higher energy than thermal reactions (and in most cases they do not occur also in the epithermal region and are induced only by fast neutrons).

A simple example of the advantage of using neutron filters (thermal neutron absorbers) in activation analysis is seen in Figure 5(a) and (b), which shows the \(\gamma\)-ray spectra of a sample of blood serum, activated with reactor neutrons once within a cadmium wrapping and once without any absorber (bare irradiation). In the case of activation without a Cd absorber, the Compton-scattered photons of the major elements Na and Cl cover the peaks of bromine and iodine (bromine can be determined only after a delay of several days while the shorter-lived iodine cannot be determined instrumentally and can be determined only after chemical separation). The activation with epithermal neutrons (Cd cover) shows clearly the peaks of \(\text{Br}\) and \(\text{I}\). A more complicated (geological) sample irradiated with and without a Cd cover is shown in Figure 6.

Owing to the presence of both thermal and epithermal neutrons, the product \(\phi\) in Equation (28) should be replaced by the term \(\phi_{th}\sigma_{th} + \phi_{epi}I_0\), where \(\phi_{th}\) and \(\sigma_{th}\) are the flux and cross-section of the reaction with thermal neutrons and \(\phi_{epi}\) and \(I_0\) [the resonance integral of the
(n,γ) reaction] are defined by Equations (51) and (52):

\[ \phi_{\text{epi}} = \int \frac{\text{total epithermal flux}}{1\text{MeV}} \frac{dE}{E} \]  

\[ I_0 = \frac{1\text{MeV}}{0.55\text{eV}} \int \frac{\sigma(E)}{E} dE \]  

The boundaries of 0.55 eV and 1 MeV were chosen since neutrons with energies above 1 MeV are categorized as fast neutrons rather than epithermal neutrons, and 0.55 eV as it is the cut-off in neutron absorption by Cd, the main filter used to capture thermal neutrons.

The epithermal activation properties of a nuclide can be expressed by the ratio \( I_0 / \sigma_{\text{th}} \), or by means of the absorber ratio. The absorber ratio is the ratio of the activities of this nuclide irradiated once bare (without a cover) and once covered by an absorber of thermal neutrons. Thus the cadmium ratio is given by Equation (53):

\[ R_{\text{Cd}} = \frac{\phi_{\text{th}} \sigma_{\text{th}} + \phi_{\text{epi}} I_0}{\phi_{\text{th}} I_0} = 1 + \frac{\phi_{\text{th}} \sigma_{\text{th}}}{\phi_{\text{epi}} I_0} \]  

The most important fact is not only how the insertion of an absorber of the thermal neutrons influences the activity of the specific measured nuclide, but also how it influences the interfering nuclides. Hence it would be advantageous to analyze an element by epithermal neutron activation analysis (ENAA) rather than by using the whole spectrum of reactor neutrons for activation [reactor neutron activation analysis (RNAA)] only if its ratio of resonance integral to thermal neutron cross-section, \( I_0 / \sigma_{\text{th}} \), is larger than this ratio for the interfering elements. Several criteria have been suggested to measure the advantage of ENAA over RNAA, as follows.

5.6.1 Brune and Jirlow’s Advantage Factor

Brune and Jirlow(45) suggested the use as an advantage factor for ENAA activation of the ratio between the cadmium ratio of the measured nuclide and the interfering nuclide [Equation 54]:

\[ F_{\text{BJ}} = \frac{R_{\text{Cd}}^*}{R_{\text{Cd}}^0} \]  

where \( R_{\text{Cd}} \) is the cadmium ratio as defined previously and the superscripts 0 and i stand for the measured and the interfering nuclides, respectively. This is the most commonly used advantage factor and several tables of this factor for many nuclides have appeared in the literature for cadmium absorbers and for boron absorbers.\(^{45–48}\)

5.6.2 Parry’s ’Improvement Factor’

Parry(49) pointed out that while the advantage factor describes well the increase in the signal-to-noise ratio, it does not consider the decrease in the activity of the analyzed element due to the elimination of the activation by the thermal neutrons and hence does not treat the larger error resulting from the lower counting statistics. Parry suggested that the true criterion should be the improvement in the detection sensitivity. The lower detection limit, \( L_D \), for a radioactivity measurement, i.e. the minimum signal which can be detected above the background at the 95% confidence level is given by Equation (55):\(^{50}\)

\[ L_D = 2.33 \sqrt{B} \]

where \( B \) is the background activity. The minimum detected mass in activation analysis (sensitivity) is given by Equation (56):

\[ M_D = \frac{A}{L_D} = \frac{A}{2.33 \sqrt{B}} \]

where \( A \) is the specific activity of the analyzed element under the experimental conditions for the activation and detection. Since \( A \) is proportional to the activity of the analyzed element and since \( B \) is due mainly to the interfering nuclide, Parry suggested that the improvement factor, \( f_p \), is given by Equation (57):

\[ f_p = \frac{R_{\text{Cd}}}{R_{\text{Cd}}^0} \]
5.6.3 Bem and Ryan’s Advantage Factor

Bem and Ryan (51) in 1981 followed the same trend of thinking as Parry; however, they suggested that the advantage factor should describe the improvement of the relative standard deviation of the counts. If the net counts (baseline corrected counts) is N and the background count is B, the advantage factor is given by Equation (58):

\[ f_{BR} = \frac{1}{N} + \frac{2B}{N^2} \left[ \frac{1}{N} + \frac{2B}{N^2} \right]^{1/2} \]  

(58)

where the subscripts i and 0 have the same meaning as the superscripts earlier.

When the background is mainly due to the interfering radionuclide, Bem and Ryan’s advantage factor is equal to that of Parry. The correlation of Parry’s advantage factor with that of Brune and Jirlow can be seen from Equation (59):

\[ f_p = \frac{f_{BJ}}{\sqrt{R_{Cd}^2}} \]  

(59)

Therefore, Parry’s advantage factor is always smaller than that of Brune and Jirlow.

5.6.4 Tian and Ehmann’s Generalized Advantage Factor

Tian and Ehmann (52) criticized Bem and Ryan’s criterion (and consequently Parry’s) on the grounds that in practice, in INAA, the limit on the number of counts is not due to the activity of the analyte, but rather to problems associated with the high counting rate. A high count rate leads to inferior resolution and also to problems of pile-up and dead time of the electronic system. In order to overcome these problems, the samples are measured far from the detector or are irradiated for shorter times. When the sample is activated with only epithermal neutrons, the total activity of the sample is reduced considerably, and hence the counting efficiency can be increased by using a smaller sample–detector distance, or the total counts can be increased by using larger samples or longer irradiation times. If the increase in counts (due to either count efficiency or size of the sample or length of irradiation) is given by \( G^2 \), then the generalized Tian and Ehmann’s advantage factor is given by Equation (60):

\[ f_{TE} = G \left( \frac{R_{Cd}^2}{R_{Cd}^2} \right) \]  

If \( G = 1 \), \( f_{TE} = f_p \), and if \( G = \sqrt{R_{Cd}^2} \), then \( f_{TE} = f_{BJ} \).

The last case is the practical one, since both in the thermal activation and in the epithermal activation, the counting efficiency is usually chosen to obtain the maximum total counting rate allowable by the dead-time correction device. This generalized approach of Tian and Ehmann gives a firmer basis for the widely used definition of Brune and Jirlow.

5.6.5 Thermal Neutron Absorbers

The main absorbers for the thermal neutrons are cadmium and boron owing to their high cross-section for reaction with thermal neutrons. The variation of the cross-section with the energy is different for Cd and for B, hence an intelligent choice of an absorber (also sometimes called a filter) will lead to optimized detection of some nuclides. (53)

In some cases, one absorber is used and in others a combination of two absorbers, e.g., Cd + B. (49,53,54) In some experiments, filters which absorb the epithermal neutrons in some regions are used, allowing more selectivity for some elements. (55)

Since the main absorbers are boron and cadmium, it is very important to compare them from the technical point of view. The absorber can be used as a covering sheet, wrapping the sample in it, mainly in the case of cadmium for which metallic sheets are commercially available, or as a capsule built from these materials, or as a mixture with the sample, used with \( \text{B}_2\text{O}_3 \), or as a permanent lined installation inside one of the irradiation ports of the reactor. The use of absorber-lined ports has the disadvantages that (1) scattered thermal neutrons can come from angles which are not covered by the lining of the absorber, leading to lower absorber ratios, whereas when the absorber is used as a capsule or wrapping, it is covered from all angles, and (2) the capsule in which the sample is held during the pneumatic transfer and which usually is made of polyethylene leads to partial thermalization of the epithermal neutrons. On the other hand, the use of an absorber-built capsule or wrapping suffers from the disadvantages of the absorption reactions. Cadmium is activated to short- and long-lived nuclides and the unloading and unpacking of the sample for medium- and long-lived radionuclide measurement faces radiation safety problems owing to the high radiation dose. Short-lived \( (t_{1/2} < 20–30\text{ s}) \) radionuclides cannot be measured at all in a cadmium capsule since the short half-life prohibits the safe unpacking of the vessel and the activity of the absorber is too high to allow measurement together with the filter.

While the absorption of neutrons by \( ^{10}\text{B} \) does not lead to radioactive products, the reaction \( ^{10}\text{B}(n,\alpha)^7\text{Li} \) is very exergic \( (Q = 2.792\text{ MeV}) \) and the samples are heated considerably. Stroube et al. (57) found that in the 20-MW reactor at the former US National Bureau of
Standards (NBS), thermal heating of the boron nitride vessel limited the length of irradiation for freeze-dried foods to 4 s and prevented completely safe irradiation of wet food. When biological samples are irradiated, this heating accelerates the thermal decomposition of organic compounds, producing high pressure in the sample container, when airtight sealed, which may explode and contaminate or even ruin the irradiation port. In other cases, elements may be volatilized and lost. In order to avoid these effects, the time of irradiation should be limited. Williamson et al.\(^{(54)}\) measured the temperature inside a polyethylene rabbit inserted into a Cd-lined irradiation port and found that the temperature reached an equilibrium value of 90°C in about 7 min. When a BN capsule was irradiated in the same position, the measured temperature was 120°C in about 3 min and continued to rise. Ehmann et al.\(^{(58)}\) irradiated rock samples in a boron carbide filter for 20 h, keeping the sample in heat-sealed quartz ampules. Quartz, being a poor thermal conductor, keeps the sample from being highly heated; this solution is good for geological samples but will probably not suffice for biological samples. Chisela et al.\(^{(59)}\) studied the temperature in a sintered BC capsule in an air-cooled irradiation facility and found the capsule to reach steady-state temperatures of 163°C and 194°C for 4.0- and 5.0-MW reactors, respectively. When a permanent installation from powdered B\(_4\)C was made with water coolant, the temperature reached not more than 50°C.

The use of a permanent lining of absorber also has the disadvantage of reducing the total flux of the neutrons in the reactor and of excessive use of the nuclear fuel. A possible advantage of boron over cadmium is the reuse of the same filter in subsequent irradiation. Cadmium filters usually cannot be reused, at least immediately, owing to the long-lived radioactivity produced in cadmium during irradiation. The activity produced in boron filters is small and is due only to contamination in the boron. However, the use of boron filters is limited in many cases to not high total doses of neutrons owing to structural failure of the capsule, probably owing to excessive formation of helium gas from the \(^{10}\)B(n,\(\alpha\))\(^7\)Li reaction. Cadmium filters are easily made from metallic cadmium sheets of about 1 mm thickness. Boron is a difficult material to machine and Stuart and Ryan\(^{(60)}\) prepared boron shields by forming a mixture of boron carbide powder and paraffin wax. The mixture was heated to 70°C (paraffin melting point = 56°C) and cast into cylindrical forms. A central hole was made in the form as it solidified by using a heated rod of appropriate diameter. The hole was not made through the whole length of the cylinder, in order to obtain a cylindrical capsule with a central cavity closed at one end. The other end was closed with a top made from the same material. Parry\(^{(47)}\) used the same method, but instead of using boron carbide, she used B powder. It should be mentioned that the paraffin causes a small thermalization of the epithermal neutrons. The best machinable refractory boron compound is BN,\(^{(61)}\) and consequently many of the studies with boron filters were made using BN capsules. Ehmann et al.\(^{(58)}\) suggested that BN should not be used owing to the relatively high cross-section of 1.81 b for the \(^{14}\)N(n,p)\(^{14}\)C reaction which leads to the formation of an appreciable amount of the long-lived radioactive \(^{14}\)C, but rather boron carbide, another refractory compound of boron, should be used. Unfortunately, boron carbide is extremely hard and is not machinable, and a capsule can be made only by the hot pressing process.

One of the disadvantages of boron filters is the impurities found in boron powder, as discussed in detail by Bem and Ryan.\(^{(51)}\) However, if a boron capsule is used together with a permanently installed Cd lining, the interferences due to the activities of \(^{28}\)Al, \(^{56}\)Mn and \(^{38}\)Cl from the boron contaminants are significantly reduced.\(^{(47)}\) Both cadmium and boron have high absorption cross-sections for low-energy neutrons; however, the energy dependences of the cross-sections differ considerably. Cadmium approaches a perfect sharp filter for the thermal region and has some resonance in the epithermal range, whereas boron behaves as almost a perfect 1/\(v\) absorber with no sharp energy cut-off. Although the cross-section for neutron capture by boron is lower than the cross-section for absorption by cadmium in the lower energy range of 0.01–1 eV, it can be compensated for by using thicker boron absorbers. A 0.25 cm thick boron shield is sufficient to stop practically all the thermal neutrons. The effective cut-off energy is almost independent of the thickness of the Cd absorber whereas it increases considerably with increasing thickness of the boron absorber.

### 5.7 Fast Neutron Instrumental Neutron Activation Analysis

The reactions that occur with fast neutrons with energy usually in the megaelectronvolt range should be looked upon in two ways: (1) the use of these reactions for the determination of some elements and (2) the possible interference of these reactions in the determination of some elements by (n,\(\gamma\)) reactions, due to the formation of the same nuclide as was shown earlier dealing with nuclear interferences. These interferences can be solved only by the use of double irradiation, one with a bare core and one inside a Cd or B filter, and calculating the contribution of each element. The same treatment is usually applied with the use of (n,p) and (n,\(\alpha\)) reactions in the determination of some elements. The main advantage of these reactions is that they produce nuclides different from those produced by (n,\(\gamma\)) reactions. Consequently,
they may lead to a faster determination in the case of producing a short-lived nuclide rather than the long-lived nuclide produced in (n,γ) reactions. In other cases, they may allow the determination of elements which cannot be measured via (n,γ) reactions since the radionuclide produced is only a β emitter.

5.7.1 Rapid Determination of Iron

Figure 7 shows the γ-ray spectrum of an iron sample irradiated for a short time. As can be seen, the peak of 847-keV γ-rays of 56Mn due to the 56Fe(n,p)56Mn reaction is considerably higher than the 59Fe(n,γ)59Fe 1099-keV peak. Hence the use of (n,p) reactions for irradiation with reactor neutrons will be considerably higher than the 58Fe(n,γ) reactions. In the case of silicon [stable isotopes 28Si (92.2%), 29Si (4.7%) and 30Si (3.1%)], the only radionuclide produced by the (n,γ) reaction is 31Si, which is almost only a β emitter. Its very low intensity of γ-rays (1266 keV, 0.07%) together with the low abundance of 30Si and the low cross-section for radiative capture (0.11 b) permit only the determination of relatively large amounts of silicon. However, activation with epithermal neutrons leads also to the formation of 28Al via both 31P(n,p)28Al and 28Si(n,p)28Al reactions and of 29Al by the 29Si(n,p)29Al reaction. 28Al is also produced by the 27Al(n,γ)28Al reaction. This leads to a procedure for the determination of Si from the activity of 29Al, which is produced only from silicon, using the activities of 28Al from activation with a Cd filter and without a filter to determine the concentration of both aluminum and phosphorus.

However, the activity of 29Al produced for Si is almost two orders of magnitude less than the activity of 28Al produced from it. Hence the use of 29Al will both limit the minimum amount of silicon that can be determined and will reduce the accuracy of the measurement. Another problem associated with the measurement of 29Al is that its main γ line is the 1273-keV line, which suffers from the interferences of the SE peak of the more abundant 28Al at 1268 keV.

However, when the concentration of Si is high, silicon can be determined by the 30Si(n,p)30Al reaction, as was done by Hancock for the measurement of silicon in pottery using a Cd shield to decrease the formation of 28Al. The samples were allowed to decay for 17–20 min before counting, to decrease the 28Al activity further. Ördög et al. measured in that way the concentration of silicon in very small inhomogeneous lymph-node samples. The concentration

\[
C_E = \frac{F_E P_F + M_R P_M}{100} \tag{62}
\]

where \(C_R\) and \(C_E\) are the activities induced by reactor neutrons and epithermal neutrons, respectively. The solution of these two equation gives Equations (63) and (64):

\[
P_F = \frac{M_E C_R - M_R C_E}{\Delta} \tag{63}
\]

\[
P_M = \frac{F_R C_E - F_E C_R}{\Delta} \tag{64}
\]

5.7.2 Determination of Phosphorus and Silicon

Thermal neutron activation cannot be used for the determination of phosphorus and silicon. A radiative capture (n,γ) reaction with the only stable isotope of P leads to the formation of 32P, which is a pure β emitter. In the case of silicon [stable isotopes 28Si (92.2%), 29Si (4.7%) and 30Si (3.1%)], the only radionuclide produced by the (n,γ) reaction is 31Si, which is almost only a β emitter. Its very low intensity of γ-rays (1266 keV, 0.07%) together with the low abundance of 30Si and the low cross-section for radiative capture (0.11 b) permit only the determination of relatively large amounts of silicon. However, activation with epithermal neutrons leads also to the formation of 28Al via both 31P(n,p)28Al and 28Si(n,p)28Al reactions and of 29Al by the 29Si(n,p)29Al reaction. 28Al is also produced by the 27Al(n,γ)28Al reaction. This leads to a procedure for the determination of Si from the activity of 29Al, which is produced only from silicon, using the activities of 28Al from activation with a Cd filter and without a filter to determine the concentration of both aluminum and phosphorus.

However, the activity of 29Al produced for Si is almost two orders of magnitude less than the activity of 28Al produced from it. Hence the use of 29Al will both limit the minimum amount of silicon that can be determined and will reduce the accuracy of the measurement. Another problem associated with the measurement of 29Al is that its main γ line is the 1273-keV line, which suffers from the interference of the SE peak of the more abundant 28Al at 1268 keV.

However, when the concentration of Si is high, silicon can be determined by the 30Si(n,p)30Al reaction, as was done by Hancock for the measurement of silicon in pottery using a Cd shield to decrease the formation of 28Al. The samples were allowed to decay for 17–20 min before counting, to decrease the 28Al activity further. Ördög et al. measured in that way the concentration of silicon in very small inhomogeneous lymph-node samples. The concentration...
of P was determined spectrophotometrically by the molybdenum blue method and hence the concentration of Si and Al can be found from the $^{28}$Al activity induced by both epithermal activation (Cd cover) and reactor neutron irradiation. Another way was suggested by Alfassi and Lavi,\textsuperscript{(65)} who used the simultaneous determination of $^{27}$Mg and $^{28}$Al, each of them for both reactor activation and irradiation with only epithermal neutrons, to measure simultaneously Mg, Al, Si and P. Each of these radionuclides can be formed by three reactions (Scheme 5).

![Scheme 5](https://via.placeholder.com/150)

The concentration of the four elements Mg, Al, Si and P can be obtained from a solution of the four equations for the four measured activities (844 keV due to $^{27}$Mg and 1778 keV due to $^{28}$Al, each without a filter and with a cadmium absorber). The specific activity (measured counts per gram of the element under the experimental set-up) will be assigned by three letters, the first giving the target element, the second the element formed and the third ($R$ or $E$) indicating whether the activation has been done by reactor neutrons (without an absorber) or by epithermal neutrons (with a cadmium absorber). Thus, for example, SAR means the specific activity of $^{28}$Al produced from silicon by reactor neutrons. The activities measured per gram of sample are also represented by three letters, the first one is always $C$, and the second and the third have the same meanings as for specific activities. If the concentrations of Mg, Al, Si and P are given by $f_{\text{Mg}}$, $f_{\text{Al}}$, $f_{\text{Si}}$ and $f_p$ in weight fractions, then the four appropriate equations are represented by Equations (65–68):

$$ CMR = MMR_{\text{Mg}} + AMR_{\text{Al}} + SMR_{\text{Si}} $$  \hspace{1cm} (65)  
$$ CME = MME_{\text{Mg}} + AME_{\text{Al}} + SME_{\text{Si}} $$  \hspace{1cm} (66)  
$$ CAR = AAR_{\text{Al}} + SAR_{\text{Si}} + PAR_p $$  \hspace{1cm} (67)  
$$ CAE = AAE_{\text{Al}} + SAE_{\text{Si}} + PAE_{p} $$  \hspace{1cm} (68)

### 5.8 Instrumental Neutron Activation Analysis with Emissions Other than $\gamma$ Emission

As written earlier, in most delayed activation analysis only the $\gamma$ emission is measured, since it is difficult to distinguish between $\beta^-$ emitters, owing to their extended spectra rather than monoenergetic emission, X-ray emission is less penetrating and neutron emission is very rare. However, all these emissions can be used in special cases. For $\beta^-$, it was shown that both for biological samples\textsuperscript{(66)} and most geological samples,\textsuperscript{(67)} owing to the higher concentration of P the main relatively long-lived $\beta^-$ emitter is $^{32}$P, and after 10 days more than 95% of the $\beta^-$ emission is due to $^{32}$P, and hence the total $\beta^-$ measurement can be used for the determination of P.

#### 5.8.1 X-Rays\textsuperscript{(68)}

X-rays suffer from two disadvantages, which can be turned to advantage in special cases. First, the range of X-rays is fairly short and only those emitted from the first few micrometers of the sample can be detected. This is disadvantageous when the whole bulk concentration is needed. However, it is advantageous when only the first few micrometers are important and when only those emitting $\gamma$-rays. This is disadvantageous since fewer elements can be determined in this method. However, if the major elements of the sample, which interfere with the measurement of the trace elements, do not emit X-rays, the few elements which emit X-rays can be determined even at low concentration owing to the lower background.

Owing to the low penetration of X-rays, the samples used for X-ray measurements should be very thin. The X-rays can be due to internal conversion (X-rays of the $Z$ of the IRN), EC (X-rays of $Z - 1$ element) or internal conversion after a $\beta$ decay ($Z + 1$ element). In $\gamma$-ray spectrometry the electrons emitted by the active sample are stopped by a thin Perspex or aluminum foil as the electrons emitted by the active sample are less penetrating than $\gamma$-rays. In the case of low-energy X-rays, they are less penetrating than some of the electrons and the electrons should be removed by a magnetic field.\textsuperscript{(69–71)} X-ray measurements have been used mainly for the determination of rare earths in geological samples,\textsuperscript{(72–74)} copper\textsuperscript{(75)} and bromine\textsuperscript{(76)} in biological and geological samples, but also other elements, such as Nb in steel\textsuperscript{(77)} and Co and Hg in Dead Sea water,\textsuperscript{(78)} have been determined.

#### 5.8.2 Neutrons\textsuperscript{(79)}

Delayed neutrons are emitted from only very few radionuclides. In many cases the radionuclide decays by both $\beta^-$ and neutron emission. For example, $^{87}$Br decays 2.8% by neutron emission while $^{88}$Br decays 6.6% by neutron emission and $^{88}$Se only 0.8%. $^{86}$Br decays 25% by neutron emission. At least 57 radionuclides which emit neutrons are known, but none of them is
formed by an \((n,\gamma)\) reaction since the nuclides should be more than one neutron further from the line of stability in order to emit neutrons. However, those radionuclides can be formed in a neutron-induced fission of fissile nuclides such as \(^{235}\text{U}\), since the heavy elements have a higher percentage of neutrons in the nucleus. This is the reason why activation analysis followed by measurement of neutrons is used for the determination of only U and Th. Since other elements do not produce neutron emitters, the background from other elements is very small. The neutrons are measured (after their moderation in a paraffin layer) by BF\(_3\) counters. These are gaseous ionization chambers which measure the \(\alpha\)-particles formed by the \(^{10}\text{B}(n,\alpha)^{7}\text{Li}\) reaction. Outside \(\alpha\)-particles are not able to penetrate the counter walls. At least 57 delayed neutron emitters are formed in the neutron-induced fission with half-lives ranging from 0.08 to 55.6 s. In order to get rid of the \(^{17}\text{N} (4.16 \text{ s})\) and \(^{16}\text{O} (2.67 \text{ s})\) neutrons, the determination of the emitted neutrons is done only for those which have half-lives longer than about 10 s, by delaying the counting for 30–60 s.\(^{60,81}\)

### 5.9 Depth Profiling by Instrumental Neutron Activation Analysis

Depth profiling involves the measurement of the concentration of a trace element as a function of its distance from the surface of the sample. This can be done by a destructive method in which the whole sample is activated and then divided into a number of sections of varying distances from the surface, either by gradual slow dissolution or by gradual milling and grinding (for each layer, its thickness and \(\gamma\) or \(\beta\) activity of the various elements are measured). Many samples are too important to be destroyed in the measurement. Using \((n,\alpha)\) or \((n,p)\) reactions, the depth profiling can be done nondestructively. The emitted charged particle \((\alpha\text{ or } p)\) has a definite kinetic energy. This particle, while transversing in the material, from its place of formation inside the sample to the detector positioned in front of the sample, loses part of its energy, depending on the distance it traveled in the sample. From the measured energy, the distance from the surface can be calculated. Thus, the energy spectrum measured for this particle is related to the concentration depth profile of the element, which is responsible for this nuclear reaction.

In order to allow the measurement of low concentrations, the nuclear reaction should have a high cross-section of the order of at least 10 b. These high cross-sections rule out most elements and only very few elements can be determined.

The method was developed in 1972 by Ziegler et al.\(^{82}\) for the determination of boron due to the high cross-section of the \(^{10}\text{B}(n,\alpha)^{7}\text{Li}\) (\(\sigma = 3837 \text{ b}\)). This cross-section is five orders of magnitude larger than that of almost any other stable nuclide for \((n,\alpha)\) reactions (except \(^{6}\text{Li}\)). The measured sample is placed in a vacuum chamber (pressure \(< 5 \times 10^{-6} \text{ Torr}\)). They needed only about \(10^{11}\) neutrons to detect a concentration of 100 ppm of boron in a 2-cm Si wafer. The \(^{7}\text{Li}\) is produced in both the ground state (6%) and in the 479-keV excited state (94%). The energy is distributed between the \(\alpha\)-particle and the \(^{7}\text{Li}\) according to their masses (1471 and 839 keV for \(^{4}\text{He}\) and \(^{7}\text{Li}\) in the reaction leading to the excited states). The bombarding thermal neutron passes through the Si wafer (170 \(\mu\text{m}\) thick) with negligible attenuation, so that the reaction efficiency is independent of the depth. The neutron beam was collimated to produce a spot 1 cm radius at the target chamber (neutron flux \(2.3 \times 10^{8} \text{n cm}^{-2} \text{s}^{-1}\)). The targets were mounted at a 45° angle to the neutron beam. The \(\alpha\)-particles were detected by a surface barrier detector subtending an angle of 19 msr and was specially fabricated to have a low \(\gamma\) and electron background and to be able to measure the spectrum of the \(\alpha\)-particles in the presence of \(^{7}\text{Li}\), although this led to poorer energy resolution for the \(\alpha\)-particles [full width at half-maximum (fwhm) \(\approx 20 \text{ keV}\) instead of 12–14 keV]. The depth of the boron is determined by the energy loss of the 1471-keV \(\alpha\)-particles using the known specific energy loss, \(dE/dx\). An energy, \(E_{i}\), parallel to depth is given by Equation (69):

\[
\text{depth} = \frac{E_{i}}{1471} \frac{dE}{dx}^{-1}\, dE
\]

Ziegler et al.\(^{82}\) measured the energy spectra of \(10^{15} - 10^{16}\) \(^{10}\text{B}\) atoms per square centimeter and calculated a concentration resolution of 3 ppm and a depth resolution of 20 nm. Müller et al.\(^{83}\) used the high-flux reactor of ILL, Grenoble, France, with a collimated flux of 1.04 \(\times 10^{9} \text{n cm}^{-2} \text{s}^{-1}\) and 1.5 cm diameter, a detector with resolution better than 16 keV for the 1471-keV peak. For a counting time of 1000 min, \(10^{11}\) \(^{10}\text{B}\) atoms per square centimeter will lead to about 110 integral counts. This is enough for measuring total boron concentration but not for profile determination and they estimated that for profile determination the minimum required concentration is \(10^{12} \text{B}\) atoms per square centimeter. They measured the concentration depth profiles of boron in silicon wafers implanted with \(10^{12}, 10^{13}\) and \(10^{14}\) \(^{10}\text{B}\) atoms per square centimeter and the accuracy of the depth determination was about 25 nm. It should be remembered that this is for \(^{10}\text{B}\) atoms whereas they constitute only 20% of the natural boron atoms. Kvittek et al.\(^{84}\) studied the boron concentration profile in Si using the spectra of both
α-particles and 7Li particles. As can be expected from the higher \( \frac{dE}{dx} \), the spatial resolution obtained with the 839-keV 7Li particle is better than that obtained by using the 1431-keV \(^4\)He line (by about 30%). However, in a later work, they explained(85) that in spite of the better resolution of the 7Li profiling, the fact that the 7Li line is located in the high-background region of the measured spectra often makes the profile analysis by this method difficult. In order to obtain better resolution they suggested measuring the α-spectra with different tilting angles.

Biersack et al.(86) discussed the achievable depth resolution and the main sources of uncertainties. They pointed out four main inherent uncertainties: (1) the uncertainty in the angle \( \theta \) between the point of reaction and point of detection as the particle travel distance \( L, \quad L = x/\cos \theta \), where \( x \) is the depth of the target atom; (2) the uncertainty in the energy resolution of the detector; (3) the uncertainty in energy loss due to energy loss straggling, assuming a fixed pathlength, \( L \); and (4) uncertainty due to multiple angular scattering. They concluded that for (n,α) reactions, a depth resolution of 5 nm is feasible, and 10-nm depth resolution is feasible for (n,p) reactions.

Apart from B, the only element which can be determined in this way using the natural abundance is lithium with 7.4% 7Li, having a cross-section of 940 b for the reaction \(^6\)Li(n,α) \(^T\), with an α energy of 2055 keV and a T energy of 2728 keV. Helium can be determined not for natural He but for 3He-doped substrates (stable isotope, natural abundance 0.0001%). Similarly, Na and Be can be determined with the radioactive isotopes 22Na and 7Be, respectively, owing to their high cross-section.

Downing et al.(87) gave a detailed description of the neutron depth profiling (NDP) system and summarized the available data in various systems throughout the world. Special attention was paid to minimizing the contamination of the thermal neutron beams with fast neutrons and γ-rays. The amount of the γ-rays and fast neutrons was reduced by filtering the beam through 200 mm of sapphire single crystal and an 80-mm long silicon single crystal, which led to a ratio of cadmium to gold of \( >10^4 \) and a γ intensity of 200 mrad h\(^{-1}\).

The NDP technique is quantitative and has few interferences in silicon-based materials. As a result, it is often used for calibration for other techniques. Other instrumental methods, such as secondary ion mass spectrometry (SIMS), Fourier transform infrared (FTIR) spectrometry, and Auger electron spectroscopy (AES) have greater sensitivity than NDP in most applications and better resolution in some matrices, but each of the other techniques is subject to highly interactive chemically and electronically induced artifacts. NDP can be used to calibrate the other methods and, after calibration, the better resolution of the other method can be used. Rutherford backscattering spectroscopy (RBS) and NDP complement each other as they both nondestructively analyze different compositions: RBS measures the concentration profile of heavy atoms in matrices of light atoms whereas NDP is limited to some light elements.

5.10 Practical Cases of Instrumental Neutron Activation Analysis

In section 5.4 a test case of INAA of Si was given. Si is one of the best matrices for INAA, owing to the low radioactivity induced in it by neutron irradiation, and consequently very low detection limits were obtained. This is not the case for all matrices. The following section gives details of several examples of analyses of various matrices by INAA.

Greenberg et al.(88) described the procedures adopted by the NAA group of the National Institute of Standards and Technology (NIST) in the USA. The samples are first packaged in a cleaned container. The container, depending on the type of the sample and the length of irradiation, can be polyethylene bags or vials, sealed by heating, or flame-sealed high-quality quartz (to eliminate as much as possible of the activatable sodium) or aluminum cans. The samples are irradiated in a well-moderated (by D\(_2\)O) neutron flux of \( 10^{14} \) n cm\(^{-2}\) s\(^{-1}\) using a pneumatic tube for transferring the sample to the reactor. The length of the irradiation, decay and counting depends on the analyzed elements. For one or a few elements the timings are optimized for these elements. Thus, for the determination of mercury in urine the samples (in quartz ampules) are irradiated for 1 h and counted after decay both of 5 and 20 d in order to measure the Hg content via the formation of both 197Hg (\( t_{1/2} = 64.1 \) h, \( E = 77 \) and 191 keV) and 203Hg (\( t_{1/2} = 46.59 \) d, \( E = 279 \) keV). The long decay is used to reduce the activities of Na, Cl and Br.

To measure Cl and Br in various oils, they used short irradiation of a few minutes and measured the activity of 35Cl (\( t_{1/2} = 37.2 \) min, \( E = 1642.2 \) and 2167.6 keV) after a decay of several minutes. The concentration of Br was determined via 82Br (\( t_{1/2} = 35.3 \) h, \( E = 554.3 \) and 776.5 keV) after a decay of 24 h. For lower detection limits of bromine, irradiation from several hours up to 24 h was applied.

For a complete multielement analysis (20–40 elements which can be determined by NAA), the elements are divided into three groups according to the half-lives of their IRNs: 2 min –15 h, 0.5–5 d and >5 d.

Some elements appear in more than one group. The usual scheme of irradiations, decays and counting is followed. The same sample can be used for the two irradiations.

</table>

The accuracy and precision of their determination can be found in Table 2, which gives their results for two NBS SRMs together with the certified values. The uncertainties listed represent the estimated overall analytical uncertainties at the 95% confidence level. SRM 1648 is Urban Dust and SRM 1572 is Citrus Leaves. In the column for the method, A, B and C refer to the previous scheme.

Cunningham and Stroube(89) applied INAA to 240 food composites. They irradiated with a neutron flux of 4.9 × 10¹³ n cm⁻² s⁻¹. Two irradiations were done on each sample, one for 15 s and one for 4–5 h. For the short irradiation, a 2-min decay time and a 10-min counting time were used. For long irradiation, the decay times varied from 5 d to 4 weeks and counting times were 6–8 h. In the short irradiation they determined Ca, Cl, Cu, Ga, I, In, K, Mg, Mn, Na, S, Sr, Ti and V and in the long irradiation Ag, As, Au, Ba, Br, Cd, Ce, Co, Cr, Cs, Eu, Fe, Hf, La, Lu, Mo, Rb, Sb, Sc, Se, Sm, Ta, Th, W, Yb and Zn.

Sun and Jervis(90) used a Slowpoke reactor, which is a nuclear reactor specially designed mainly for teaching, with activation analysis and the production of small amounts of radioisotopes in mind. The reactor operates at a low power of 20 kW and has a maximum flux of 10¹² n cm⁻² s⁻¹ (Sun and Jervis used a flux of 2.5 × 10¹¹ n cm⁻² s⁻¹). An advantage of this type of reactor is its high stability (1–2% over long periods), which allows the irradiation of standards only every few days and not necessarily with each sample. Sun and Jervis(91) determined 35 elements in rocks and soils using two irradiations and three countings. Al, Ba, Ca, Cl, Dy, I, Mg, Mn, Sr, Ti, U and V were determined by 1-min irradiation followed by 5-min counting after a decay of 10–15 min. Long irradiations of 16 h were followed by 30-min counting after 4–9-d decay (As, Br, K, La, Na,
Sb, Sm, W and Yb) and 100-min counting after a decay of 15–20 d (Ce, Co, Cr, Cs, En, Fe, Hf, Ln, Nd, Rb, Sb, Sc, Se, Sn, Ta, Tb, Th, Yb and Zn). Large relative standard deviations between several samples were found for Cl (32%), Sb (24%), Ti (18%), Ba (16%) and Br (14%), but for most elements the average relative standard deviation was <10%. A similar scheme was used by the same authors for samples of coal and ashes, except that the short irradiation time for coal samples was increased to 5 min.

Iskander(92) measured the concentrations of 28 elements in tobacco and cigarette paper. Samples were irradiated for two irradiation periods, the first for 3 min and the second for 8 h with a neutron flux of $2 \times 10^{12}$ n cm$^{-2}$ s$^{-1}$ from a TRIGA Mark I reactor. The sample was irradiated for 3 min and was counted for 3 min after a 1-min decay (to measure Al, V, Ti, Ca and Mg) and after an additional decay of 26 min (total decay time 30 min) was counted again for 1000 s (to determine Cl and Mn). Also, the long-irradiated samples were counted twice: 4000 s after a decay of 12 h (to determine K, Na, As, Br and La) and 40000 s after a decay of 21 d (Ba, Rb, Th, Cr, Ce, Hf, Fe, Sb, Sr, Ni, Sc, Se, Sn, Ta, Tb, Th, Yb and Zn).

McOrist et al.93,94 studied trace element concentrations in various Australian opals. They irradiated their samples twice, for 1 min at a thermal flux of $5 \times 10^{13}$ n cm$^{-2}$ s$^{-1}$ and for 18 h at a thermal flux of $5 \times 10^{12}$ n cm$^{-2}$ s$^{-1}$. Each irradiated sample was counted twice. The short-irradiated samples were counted for 10 min after a 20-min decay and for 45 min after a decay of 24 h. After the long irradiation, the samples were counted for 2 and 4 h after 7 and 28 d of decay, respectively.

Wallner and Katzberger95 studied the concentrations of 14 elements in spruce tree rings and needles from an area where an Al refinery used to be. Al, Mn, Ca and Cl were determined by 3–7 min of irradiation at a thermal neutron flux of $5 \times 10^{10}$ n cm$^{-2}$ s$^{-1}$. They calculated that for Al, assuming that the main interference for its 1779-keV line is from the Compton-scattered photons of the

a d means days, h means hours, s = seconds, m = minutes, mon = months, E means irradiation with epithermal neutrons.

2113-keV line of $^{56}$Mn, the optimum irradiation time is 4 min. However, for samples with a low Ca content longer irradiations up to 7 min were used. Na, K, Rb, Ba, Zn, Fe, Sc, Cr, Co and Br were determined by 10 h of irradiation with a thermal neutron flux of $8 \times 10^{13}$ n cm$^{-2}$ s$^{-1}$. The samples were counted three times, after a decay of 4–5 d (Na and K), a decay of 7 d (Br and Ca) and a decay of 14 d (Ba, Co, Cr, Fe, Rb, Sc and Zn).

Oddone et al. studied the elemental content of Anatolian obsidians, volcanic glasses, by INAA using both thermal and epithermal neutrons. Mg, K, Ca, Ti, Mn, As and Dy were determined by 2 min of irradiation at a thermal neutron flux of $1 \times 10^{12}$ n cm$^{-2}$ s$^{-1}$ in a TRIGA Mark II reactor, 250 kW. The sample was counted six times after decays of 0.5, 10, 30, 120, 480 and 960 min. The longer the decay time, the longer was the counting. Al and Si were determined by repeating the short-time irradiation for a sample wrapped in a 10-mm thick Cd foil. Both Al and Si were determined from the 1779-keV line of $^{28}$Al, using the epithermal neutron activation reaction $^{28}$Si(n,p)$^{28}$Al. Na, Ca, Sc, Cr, Fe, Co, Zn, Se, Rb, Zr, Nb, Sb, Ba, La, Ce, Nd, Sm, Eu, Gd, Tb, Ho, Yb, Lu, Hf, Ta and Th were determined by irradiation for 20 h. The samples were counted five times after decays of 3, 6, 24, 48 and 96 d. Epithermal neutron INAA was applied also with long irradiation (using samples inside a 1.5-mm thick Cd box) in order to reduce the interferences from elements with low resonance integrals and high thermal cross-section (small $I_0/\sigma$ ratio). The samples were irradiated for 40 h and counted five times after decays of 3, 6, 12, 24 and 48 d. The epithermal neutron INAA improved the sensitivity and accuracy of the measurement of Zn, Se, Rb, Zr, Nb, Sb, Cs, Ba, Gd, Tb, Ho, Tm, Yb, Hf, Ta and Th. Ni, Sr and U, which could not be measured by thermal INAA, could be determined by the epithermal INAA.

Sato suggested four different schemes of timings for the determination of various elements in biological samples (three times of irradiation with the last one being counted twice, after different decay times). His suggestion for the various elements is given in Table 3. Table 4 gives three examples from the literature, for the irradiation of biological samples together with their timings and the limits of detection of some elements via INAA.

INSTRUMENTAL NEUTRON ACTIVATION ANALYSIS

66. E. Steinnes, Talanta, 14, 753 (1967).

Biological monitoring uses sophisticated analytical techniques for the accurate and precise determination of metals in blood and urine. This provides occupational health professionals with the means to monitor worker exposure to toxic metals. For metals such as lead, cadmium, and mercury, good correlations have been found between the level of the metal in blood and/or urine and health impairment.

Analytical techniques such as graphite furnace atomic absorption spectroscopy (GFAAS) and inductively coupled plasma mass spectrometry (ICP/MS) have been widely used to determine metals in biological samples. Since metals may exist in different forms in blood and urine, chromatographic separation combined with spectroscopic detection has been used to determine metal species. Biological monitoring is an example of how modern analytical chemistry has provided the tools needed to protect the health of workers.
1 INTRODUCTION

Exposure to metals occurs in a number of industries from the mining, roasting, and smelting of ores, to steel and metal alloy production, to the manufacture of batteries and silicon chips. The industries may be very large, such as factories producing thousands of lead batteries each day, or a small one-room electroplating shop, or a dentist’s surgery filling a tooth with a mercury amalgam. The literature is replete with examples of toxic exposures in the above-mentioned cases (and many others). Unfortunately, the toxic exposure is not limited to workers using metals in industry but can occur in homeowners growing vegetables in a backyard garden or in a child playing in his room. The easily identifiable villain in these two cases is lead, a metal now ubiquitous in our environment. In fact, many of the metals of concern in industrial exposure, arsenic, cadmium, chromium, mercury, selenium, and vanadium, are also of concern in the environment owing to the activities of humankind throughout the course of human history.

Biological monitoring provides health care professionals with an important tool that can be used to assess metal exposure.\(^{1}\) Advances in analytical chemistry have played a major role in the identification and quantification of metals in environmental and biological samples. Detection limits/quantitation limits continue to improve along with the accuracy and the reliability of the measurements. These improvements allow us not only to better assess the exposure of workers in a manufacturing plant, but also to assess the exposure of those individuals that live in the vicinity of that plant.

2 BACKGROUND

Biological monitoring can be defined as the measurement of chemical markers in biological media (blood, urine, expired air) that are indicative of external exposure to chemical agents.\(^{2}\) The chemical marker may be the originally absorbed chemical, (e.g. Pb in the case of a battery worker), a metabolite of the absorbed chemical (most common in the case of organic solvent exposure), or a biochemical response induced by the chemical, (e.g. zinc protoporphyrin (ZPP)).\(^{3}\) The first two cases are referred to as biological markers of exposure, and the latter is a biological marker of effect. Ideally, for every biomarker of exposure there should be a biomarker of effect. Two excellent examples of this are the two metals for which the United States Occupational Safety and Health Administration (OSHA) has mandated biological monitoring. The OSHA lead Standard (became law in 1979) requires blood-lead determinations as well as ZPP determinations.\(^{4}\) ZPP is a biomarker of effect and is an indicator of the interference by lead in the biosynthesis of heme. It is used to monitor the biochemical response in workers where the exposure is usually chronic in nature.

The other metal for which OSHA has established biological monitoring guidelines is cadmium.\(^{5}\) Blood and urine cadmium are the markers of exposure and \(\beta\)-2-microglobulin (\(\beta\)-2M) is the marker of effect. In the USA, lead and cadmium are the only cases where biological monitoring is mandated by law. Biological monitoring for lead is required by many countries throughout the world including Germany, Great Britain, Sweden, Finland, Denmark, Norway, France, and Australia. Germany has standards set for aluminum, mercury (inorganic and organic), and vanadium. The World Health Organization (WHO) has set standards for mercury in blood and urine and cadmium in urine.

3 AIR MONITORING VERSUS BIOLOGICAL MONITORING

Air sampling has been and continues to be the most common method of monitoring for chemical exposure in the workplace. In fact, air sampling has become so prominent that it is synonymous with the field of industrial hygiene. There are a number of advantages to air monitoring:

1. Air monitoring is a long-standing tradition (the first air exposure limits were set in the 1940s).
2. A large number of air-monitoring standards which have the force of law have been established.
3. Generally, there is worker acceptance of the method.
4. There are rugged analytical methods available from a number of qualified laboratories.

There are a number of significant weaknesses in using air monitoring as the only mechanism for monitoring worker exposure.\(^{6}\) These weaknesses include the inability to account for dermal and oral exposure, the inability to account for individual variation in absorption of airborne contaminants, the inability to monitor the effectiveness of personal protective equipment (PPE), and the inability to assess exposure outside the workplace. Biological monitoring has the ability to monitor worker exposure via all routes of exposure including air, dermal, and oral. For many chemicals dermal absorption can be a significant route of exposure which is completely overlooked if air monitoring alone is used. Chemicals like aromatic amines (aniline, methylenedianiline), chlorophenol, dimethylformamide, most pesticides,
and even some metals can pose a serious dermal absorption problem. OSHA is now trying to address this problem by having inspectors monitor surface contamination by taking wipe samples.

Another route often ignored is the oral route of exposure. This route can be significant for metals when workers are in a dusty environment. Contamination of the hands during work followed by eating and smoking can be a source of oral exposure. A study of cadmium workers whose hands were checked for Cd just before entering the lunch room showed significant Cd contamination. Biological monitoring is a measure of total exposure; all forms of absorption will be accounted for. Because biological monitoring uses the individual as the dosimeter of exposure, it reflects individual differences in exposure, absorption, distribution, and/or metabolism. There are significant differences in the absorption of chemicals by different people as well as by the same person under different conditions. The rate of breathing has a dramatic effect on the absorption. The harder a person works the more air he or she takes in and the more contaminant is absorbed. From light work, to moderate work, to heavy work a significant increase in absorption occurs. PPE is often the only barrier between the worker and serious health damage. However, does the worker make use of PPE all the time? Does the PPE fit properly? Is the PPE working properly, the right glove? Biological monitoring can answer these questions. Most important, there is a closer relationship between biological monitoring and health outcome than there is with external dose markers such as air monitoring.

There are some disadvantages to biological monitoring. Biological monitoring is often an invasive method, especially when the collection of blood is required. Even when biological monitoring involves the collection of urine only, the workers view this as an invasion of privacy and are concerned that the sample will be used for drug testing. The relationship between exposure to toxins in the air and the presence of toxins in the body is not fully appreciated. When all of these issues are addressed beforehand by the health professional, many of these problems disappear, and informed workers may demand this type of monitoring as protective of their health.

The last impediment to the use of biological monitoring involves the lack of biological monitoring standards. As mentioned, in the USA OSHA has mandated only two standards. The apparent reluctance of OSHA to create biological monitoring Standards was addressed in a recent paper by Rappaport. In this paper, the author points out two problem areas where biological monitoring could provide solutions. One controversial area is associated with the dose rate which is involved in setting OSHA STELs (short-term exposure limits). Using biological monitoring to study the exposure–biomarker relationship could help solve this issue. The other problem area has to do with exposure to chemicals where accumulation occurs over months of exposure. This is the case for lead. Blood lead is known to be a better indicator of exposure and disease than air lead. This argument could be extended to almost every other metal for which accumulation occurs, as well as a number of organic compounds which are long-term exposure hazards. Adding to this our ever-growing knowledge of the effects of even low-level metal exposures, the need and value of biological monitoring will become more fully appreciated.

4 AMERICAN CONFERENCE OF GOVERNMENT INDUSTRIAL HYGIENISTS BIOLOGICAL EXPOSURE INDICES™

The American Conference of Government Industrial Hygienists (ACGIH) has established a number of biological exposure indices (BEI™). The BEIs™ are reference values of biological determinants. They are:

Reference values intended as guidelines for the evaluation of potential health hazards in the practice of industrial hygiene. BEIs™ represent the levels of determinants which are most likely to be observed in specimens collected from a healthy worker who has been exposed to chemicals to the same extent as a worker with inhalation exposure to the TLV™ (threshold limit value™).

The TLVs™ are air monitoring standards established by ACGIH. The values represent the maximum airborne exposure to which a worker can be exposed for 8 h day⁻¹, 50 weeks per year, without experiencing any loss of health and/or well-being.

BEIs™ provide a means of assessing exposure from all sources. They give an individual dimension to air sampling and they can be used to determine the effectiveness of PPE. BEIs™ are based on human data from both experimental and field studies. They take into account the relationship between external and internal doses at the TLV™, as well as the relationship between internal dose and reversible health effects.

To date the ACGIH has proposed BEIs™ for the metals arsenic and soluble compounds including arsine, cadmium and inorganic compounds, chromium water-soluble fumes, cobalt, lead, mercury, and vanadium pentoxide. The following metals are under study for the establishment of BEIs™: aluminum, organic lead, manganese, nickel, and selenium.
5 DEUTSCH FORSCHUNGSGEMEINSCHAFT
BIOLGISCHER ARBEITSSTOFF-
TOLERANZ-WERT VALUES

The German government established the first biological monitoring standards in 1981 with the creation of BAT values. The BAT value “Biologischer Arbeitsstoff-Toleranz-Wert” (biological tolerance value for occupational exposures) is defined as the maximum permissible quantity of a chemical substance or its metabolites or the maximum permissible deviation from the norm of biological parameters induced by these substances in exposed humans. The BAT value is established on the basis of currently available scientific data and reflects concentrations that generally do not adversely affect the health of the worker. They are for an exposure of 8 h day\(^{-1}\), 40 h per week.\(^{[10,11]}\) BAT values have been established for the following metals: aluminum, cadmium, lead, mercury (inorganic and organic), and vanadium pentoxide. BAT values are not established for substances which are known to be carcinogenic because it is not possible to specify safe levels for such compounds. For these compounds correlations between the concentration of a substance in the air of the work area and concentrations of the substance or its metabolites in biological media have been established. The following metals are included in this list: alkali chromates, arsenic trioxide, cobalt, and nickel.

6 LEAD

Monitoring exposure to inorganic lead in the workplace involves the determination of lead in whole blood as well as ZPP. ZPP is a biomarker of effect of lead on heme synthesis in the body. The OSHA limits of lead and ZPP are: Pb < 50 \(\text{µg} \cdot \text{dL}^{-1}\), ZPP < 60 \(\text{µg} \cdot \text{dL}^{-1}\). The ACGIH BEI\(\text{m}^\text{m}\) for lead is 30 \(\text{µg} \cdot \text{dL}^{-1}\). The BAT for lead is 70 \(\text{µg} \cdot \text{dL}^{-1}\) (30 \(\text{µg} \cdot \text{dL}^{-1}\), women < 45 years). Determination of lead in urine is not a good indicator of inorganic lead exposure and is seldom used except to monitor chelation therapy. Urinary lead is useful if the exposure is due to organolead compounds. There is a BAT for organolead compounds in urine.

6.1 Biological Monitoring Analytical Methods for Lead

The determination of lead in blood is the most frequent biological monitoring analysis performed. A good way to determine the analytical methods that are used for blood lead is to refer to the various blood lead proficiency testing programs (see Table 1) that are available. Laboratories are required to participate in one or more of these programs in order to be certified able to perform this analysis. Participant reports from the various programs include information about the blood-lead method used by each laboratory. These programs include: Wisconsin/Centers for Disease Control (CDC), the College of American Pathologists (CAP), the State of New York, and le Centre de Toxicologie du Quebec. By far the most common method used is GFAAS followed by anodic stripping voltammetry (ASV). Other methods include ICP/MS, chelation extraction/flame atomic absorption spectroscopy (FAAS), and Delves Cup.

6.2 Graphite Furnace Atomic Absorption Spectroscopy

GFAAS methods involve the dilution of blood with a matrix modifier solution containing a surfactant (typically Triton X-100), ammonium phosphate, and nitric acid.\(^{[12,14–18]}\) Instrumental requirements include automated sample injection, atomization using either “wall”\(^{[13]}\) or stabilized temperature platform (also called L’vov platform)\(^{[12,14–18]}\), and most important, a background correction method. For blood-lead deuterium background correction\(^{[12,14,16,17]}\) the Smith–Hiefje background correction\(^{[18]}\) or the Zeeman background correction\(^{[12,13,15–17,19]}\) is used. Newer instrumentation using transverse Zeeman and longitudinal heating are also being used.\(^{[15]}\) Graphite furnace conditions will vary from instrument to instrument but all involve a drying step to remove water, followed by an ashing step to destroy as much organic matter as possible (the phosphate modifier allows the destruction of the blood matrix without loss of the analyte, while nitric acid would facilitate the destruction by oxidation), followed by atomization. A final high-temperature “cleaning burn” completes the cycle. An important aspect of the blood-lead determination involves calibration: aqueous standards versus matrix matched standards. Direct aqueous standardization has been used by a number of authors for calibration.\(^{[15,16,18]}\) Others have found aqueous standards unacceptable and have relied on matrix-matched standards for calibration.\(^{[12–14,17,19]}\) The ability to use aqueous standards seems to be dependent on the design of the furnace system and, especially, the graphite tube design. It is this author’s experience that matrix-matched standards provide the best accuracy for blood-lead determinations. The National Institute of Standards and Technology (NIST) has a standard reference material

for lead in blood (SRM 955b). The SRM contains blood standards at four different levels which can be used as primary standards or controls.

A number of variations in the GFAAS determination of Pb in blood have occurred which are worthy of note. Jacobson et al. did a protein precipitation step prior to furnace analysis which seemed to improve accuracy.13 D’Haese et al. used a molybdenum-treated L’vov platform to reduce matrix and spectral interferences when using deuterium background correction.14

Modern graphite furnace systems completely automate the analysis process using a computer to control the automatic calibration step, the quality control (QC) checks, and the calculation of the final result. All of the foregoing are capable of being imported directly into a Laboratory Information Management System (LIMS). QC checks can initiate automatic recalibration and sample reanalysis should a control fall out of the acceptable range.

6.3 Anodic Stripping Voltammetry

ASV has been used for blood determinations since the early 1970s and was the first micromethod for blood lead. The technique involves the dilution of blood with a special reagent to free the lead from the red cell, the plating (reduction reaction) of the lead onto a mercury-coated graphite electrode, and the stripping (oxidation reaction) of the lead from the electrode. The potential at which plating and stripping occurs is specific for lead, whereas the current generated is proportional to the amount of lead.20,21

Recently, a hand-held battery-operated instrument was approved by the US Food and Drug Administration (FDA) for the determination of lead in blood from finger stick samples. The method involves dilution of the blood with a special reagent and then placing an aliquot of the sample onto the electrode. The cycle of plating and stripping occurs and a final answer is provided. The instrument was designed for the doctors’ surgery and for the screening of subjects in the field. Correlation with graphite furnace and classical ASV methods was excellent.22

6.4 Inductively Coupled Plasma Mass Spectrometry

ICP/MS has been applied to the determination of lead in blood. The high solids content of blood can cause significant matrix problems, but the greatly improved detection limits of ICP/MS make this an ideal method of measuring lead in blood by simple dilution. Various diluents have been used including nitric acid, ammonia, and tetramethylammonium hydroxide followed by direct analysis.23–26 Isotope dilution ICP/MS, which involves adding a known amount of a rare isotope of lead to the blood sample before sample treatment, has become the reference method for lead in blood. NIST SRM 955b (lead in blood) uses isotope dilution ICP/MS to establish the true value. The method of Paschal et al. involves microwave digestion of the blood with added isotope using nitric acid followed by direct ICP/MS analysis.27 Stroh used simple dilution with an ammonia/Triton X-100 solution for the isotope dilution ICP/MS determination of Pb.28 Another interesting use of the isotope dilution method and measuring several isotopes of lead simultaneously is the fingerprint capability. Lead from different sources exhibits different isotope ratios. These ratios can be used to pinpoint the source of the lead. This procedure has been used in cases of childhood lead poisoning where the source of the contamination was in doubt.29

6.5 Other Methods

Older methods involving chelation extraction FAAS and Delves Cup are rarely used being replaced by GFAAS and ASV. Other interesting blood-lead methods include capacitively coupled microwave plasma atomic emission and electron-capture negative chemical ionization gas chromatography/mass spectrometry (GC/MS).30

7 CADMIUM

The OSHA Cadmium Standard requires monitoring for Cd in blood and urine. Cd in blood reflects recent exposure while Cd in urine reflects long-term exposure. In addition to the measurement of Cd, β-2M, a marker of renal tubular damage, is also required. The OSHA Cd Standard is blood Cd, <5 μg L⁻¹, urine Cd, <3 μg g⁻¹ creatinine, and β-2M, <300 μg g⁻¹ creatinine. The ACGIH BEI for Cd is blood Cd, 5 μg L⁻¹; urine, 5 μg g⁻¹ creatinine. The BAT for Cd is 15 μg L⁻¹ for blood and urine.

7.1 Biological Monitoring Analytical Methods for Cadmium

For the OSHA Cadmium Standard, two proficiency testing programs (see Table 2) have been established: the CAP and le Centre de Toxicologie du Quebec. Methods used for Cd are GFAAS, ICP/MS, and extraction/FAAS (two of 50).

7.2 Graphite Furnace Atomic Absorption

By far the most common methods of determining cadmium in blood and urine involve GFAAS. The

² CLIA is the Clinical Laboratory Improvement Act. HCFA is the Health Care Financing Administration.

The determination of Cd in urine involves simple dilution of the sample with dilute nitric acid followed by GFAAS without a matrix modifier³⁵,³⁶ or with a matrix modifier.¹⁴,³⁷,³⁸ Without the use of a matrix modifier, theashing/charring temperature must be carefully controlled (maximum of 400°C) or loss of Cd will result.³⁵ Use of an ammonium phosphate modifier minimizes this problem while at the same time reducing the background signal. Most methods for Cd in urine use an ammonium phosphate modifier.³⁷,³⁸ This includes the OSHA Cadmium Standard recommended method.³⁷ Calibration for the nonmodifier procedures involve the method of standard addition or, more commonly, preparation of urine-based standards.³⁵,³⁶ Employing a matrix modifier allows the use of aqueous standards for calibration.³⁷,³⁸ Chelation/extraction methods have also been used for the determination of Cd in urine. In this method, urinary Cd is chelated with hexamethylene ammonium/hexamethylene dithiocarbamidate, extracted into a mixture of diisopropyl ketone and xylene, and determined by GFAAS.³⁹ Aqueous standards prepared in glutathione and chelated/extracted like the samples are used for calibration.

For cadmium in blood, the procedures fall into two major categories: protein precipitation with nitric acid followed by direct GFAAS without matrix modifier⁴⁰,⁴¹ or direct analysis with matrix modifier.¹⁴,⁴²-⁴⁴ The OSHA-recommended method uses protein precipitation (blood) with nitric acid and direct analysis without a matrix modifier.³⁶ The major disadvantages of the precipitation method are the additional sample handling required and the increased possibility of contamination. It is for this reason that many laboratories prefer to use the simple dilution and matrix modification method.¹⁴,⁴²-⁴⁴ Standardization of Cd in blood is similar to that for urine. Nonmodifier methods use standard additions or standards prepared in blood, while modifier methods use direct aqueous calibrators in most cases, although one author recommended matrix-matched standards for blood Cd using deuterium background correction.¹⁴

7.3 Other Methods

Employing a column preconcentration technique and a slotted quartz tube mounted on the burner, Karakaya et al. successfully determined Cd in blood and urine by FAAS. The method had a detection limit of 1 µg L⁻¹.⁴⁵ Many of the ICP/MS methods mentioned earlier for the determination of lead in blood and urine are also applicable to Cd in blood and urine. The methods involve simple dilution with various diluents and ICP/MS or isotope dilution ICP/MS determination.¹⁹,³¹,³²,⁴⁶ Cd and Pb in urine were determined by differential pulse ASV following high-pressure digestion of urine with a detection limit of 1 µg L⁻¹.⁴⁷

8 MERCURY

The ACGIH BEI⁷⁰ for total inorganic mercury in urine is 35 µg g⁻¹ creatinine for preshift samples. The BEI⁷⁰ for total inorganic mercury in blood is 15 µg L⁻¹ for samples collected at the end of shift at the end of the work week. The BAT for total inorganic mercury in urine is 200 µg L⁻¹; blood is 50 µg L⁻¹. There is no BEI⁷⁰ for organic mercury exposure, for example alkyl mercury compounds; however, there is a BAT for organic mercury, which is 100 µg L⁻¹. The organomercury compounds are associated with the red cells and, therefore, must be monitored in whole blood.

8.1 Biological Monitoring Analytical Methods for Mercury

The proficiency testing program of le Centre de Toxicologie du Quebec includes both blood and urine mercury (see Table 3). Methods used by participating laboratories include cold vapor atomic absorption with acid digestion or selective reduction, cold vapor with gold film concentration atomic absorption spectroscopy (AAS), and ICP/MS.

8.2 Cold Vapor Atomic Absorption

While the volatility of elemental mercury is the major reason for the potentially easy absorption of this metal, this same characteristic provides a unique method for its measurement. Most methods for mercury involve
chemical generation and measurement of mercury vapor by atomic absorption without flame or heat of any kind, thus the name cold vapor atomic absorption spectroscopy (CVAAS). Sample preparation prior to the CVAAS determination falls into two major categories, digestion and direct reduction. One common digestion procedure involves digestion of the sample with sulfuric acid and potassium permanganate followed by reduction with stannous chloride. The US Environmental Protection Agency (EPA) Method 245.1 (manual method) and 245.2 (automated method) have been modified for the determination of Hg in urine. Digestion is achieved with a combination of nitric acid, sulfuric acid, potassium permanganate, and potassium persulfate at a temperature of 95 °C. Reduction with stannous chloride follows. The method can be used to determine Hg in a variety of biological samples including blood, urine, hair, and tissue. A flow injection procedure with on-line oxidation of the organic mercury species has been described. This method can also be used to distinguish between organic and inorganic mercury. For Hg in urine, destruction of urine with nitric acid alone just prior to stannous chloride reduction can also be used. While these methods are commonly used, a major interference in methods which use acid digestion and/or acidic reduction methods has been noted. Iodine (I⁻) interferes with the digestion/reduction method and can cause total suppression of the Hg signal. This effect is not observed in the nondigestion alkaline reduction methods.

The selective reduction methods (blood and urine) use a stannous chloride–cadmium chloride reductant under alkaline conditions to produce Hg vapor from both inorganic and organic mercury yielding total mercury. Inorganic Hg can be determined using a reductant of stannous chloride alone, also under alkaline conditions. Sodium borohydride under alkaline conditions has been used as a reductant for total Hg in blood.

For increased sensitivity a commercially available amalgamation device coupled to a hydride generation device using acidic borohydride reduction has been used for Hg in blood and urine. The Hg vapor from the reduction reaction is trapped onto gold/platinum gauze to form a Hg amalgam. The amalgam is heated to release the Hg vapor. A highly sensitive adaptation of the amalgam approach using a gold-coated quartz sand trap has been reported. In this method biological samples are digested in sealed Teflon vessels prior to reduction with stannous chloride and concentration on the gold-coated sand trap. The trap is then removed from the apparatus for later analysis. The trap is then placed in a special heating unit to release the trapped Hg and to determine it by atomic fluorescence. The detection limit is 50 pmol L⁻¹.

ICP/MS has also been successfully used for Hg in blood by simple dilution of the sample with tetramethylammonium hydroxide. Alkyl Hg compounds like methyl mercury and ethyl mercury are far more toxic than elemental and inorganic mercury compounds. Thus, it is important to be able to differentiate between the various chemical forms of mercury. A number of novel approaches have been used. Chromatographic separation of Hg²⁺, CH₃Hg⁺, and C₂H₅Hg⁺ by reversed phase liquid chromatography followed by borohydride reduction/CVAAS has been developed. An interesting procedure for the determination of inorganic mercury and monomethyl mercury in a variety of biological samples uses alkaline digestion followed by an aqueous-phase ethylation reaction with sodium tetraethylborate. The ethyl derivatives are pre-collected on a trapping column. The trapping column is thermally desorbed onto a packed GC (gas chromatography) column for separation. The compounds are decomposed to Hg⁰ with detection by CVAAS.

The applicability of capillary electrophoresis (CE) to mercury speciation has been described. Hg²⁺, CH₃Hg⁺, and C₂H₅Hg⁺, were separated by CE and detected amperometrically at the parts per billion level.

9 CHROMIUM

The ACGIH BEI™ for chromium(VI), water-soluble fume is 10 µg g⁻¹ creatinine for the increase during shift.
and 30 µg g⁻¹ creatinine, for end of shift at the end of the work week. Because it is considered a carcinogenic substance, there is no BAT for Cr(VI). However, the relationship between air levels and the corresponding level of Cr in whole blood and in urine is given. For example, at an air exposure level of 0.05 mg m⁻³ (the ACGIH TLV™) the corresponding level of Cr in whole blood is 17 µg L⁻¹ and 20 µg L⁻¹ in urine.

9.1 Biological Monitoring Analytical Methods for Chromium

The Quebec proficiency testing program includes urine chromium as one of the analytes. Of the 36 laboratories reporting values for chromium, all of them used GFAAS with either Zeeman or deuterium background correction. (Note that CAP includes serum Cr in their trace metal program).

Sample preparation for the determination of Cr in urine involves simple dilution of the sample with a dilute nitric acid/Triton X-100 solution.⁶³⁻⁶⁷ For Cr in whole blood, simple dilution is again the method of choice.⁶³,⁶⁵ Because of the very low volatility of Cr, an ashing temperature of 1200 °C is used and a matrix modifier is not necessary. Zeeman or deuterium background correction have been found to be effective. Granadillo et al. did an extensive study including sample preparation methods, deuterium and Zeeman correction, pyrolysis/atomization temperature, and wall versus platform atomization and found that no background correction is necessary for Cr in a variety of biological samples.⁶³ The method of calibration is a major source of variation for urinary and blood Cr determinations. There are three major methods, aqueous standards,⁶³,⁶⁷ the method of standard addition,⁶⁴,⁶⁵ and matrix-matched standards.⁶⁶ This author prefers the last method which involves preparation of standards in a urine matrix. The only difficulty in this method is to obtain a urine sample with low or nondetectable levels of Cr. Chromium is an ubiquitous metal and great care must be exercised to minimize contamination in every step of the analytical procedure from sample collection to final analysis.

10 COBALT

The ACGIH BEI™ for cobalt in urine is 15 µg L⁻¹, the BEI™ for blood is 1 µg L⁻¹ for samples collected at the end of shift, at the end of the work week. As with chromium, there is a relationship between air exposure and a biological level for Co and no BAT. At an air level of 0.05 mg m⁻³, a whole blood Co of 2.5 µg L⁻¹ and a urine level of 30 µg L⁻¹ are noted.

10.1 Biological Monitoring Methods for Cobalt

Methods for the determination of Co in urine use GFAAS with either direct analysis of diluted urine⁶⁸,⁶⁹ or GFAAS determination following Co chelation and extraction.⁷⁰,⁷¹ Although not as sensitive as the chelation/extraction method, direct analysis has the advantage of simplicity, and most important, a decrease in potential for contamination from reagents used in sample preparation.

The determination of Co in blood involves direct analysis of diluted whole blood.⁷² Because the difficulties of this determination include an increased detection limit compared with urine, the WHO recommends urine Co as the method of choice for Co monitoring.⁷³

11 ARSENIC

The BEI™ for inorganic arsenic and metabolites in urine is 50 µg g⁻¹ creatinine for samples collected at the end of the work week. The As BEI™ will change to 35 µg L⁻¹ in 1999. There is no BAT for As because it is considered to be a carcinogen like Cr and Co. Urinary levels of 50 µg L⁻¹ are observed after exposure to As at 0.01 mg m⁻³.

11.1 Biological Monitoring for Arsenic

Of all of the metals, As is certainly the most interesting, most complicated, and least understood. The metabolism of As is unique among all metals in proceeding by a stepwise methylation reaction.⁷⁴,⁷⁵ An unusual aspect of As metabolism is the fact that no animal model exists which can be used to study human metabolism. A wide variation among species exists ranging from certain animals where the methylation reaction is nonexistent to species where methylation is the major route and everything in between. In humans the metabolism of inorganic As has been studied extensively and proceeds by Scheme 1:

![Scheme 1]

This process apparently takes place in the liver and has always been considered to be a detoxification mechanism. Recent studies dispute this long-held belief.⁷⁶,⁷⁷ Arsenic
has been shown to cause both DNA hypomethylation in rat liver epithelial cells and DNA hypermethylation in the human p53 gene.

Proportions of each metabolite excreted for control subjects and exposed workers are shown in Table 4.\(^{(78)}\)

Methylation efficiency decreases at very high dose levels. The time course of an As\(^{3+}\) ingestion begins with the excretion of mainly inorganic arsenic for the first 0–12 h. This rapidly changes to a preponderance of dimethylarsinic acid (DMA) with DMA comprising 70–80% of the As excreted 72–96 h postingestion. In an attempted suicide at very high As\(^{3+}\) levels, 85% of the excreted As was in the inorganic form (As\(^{3+}\) and As\(^{5+}\)) at 1 day postingestion, 93% at 2 days postingestion, 63% at 3 days postingestion, 49% at 4 days postingestion, and 14% at 8 days postingestion. The corresponding DMA was 0% at 1 day, 1% at 2 days, 35% at 3 and 4 days, and 69% at 8 days postingestion.\(^{(78)}\)

Because of the good correlation between the level of exposure and urinary excretion (45–60% of the dose is excreted in 2 days), routine determination of As in urine is the best approach for monitoring occupational exposure to inorganic As. Measurement of As in urine is complicated, however, by the presence of high concentrations of As in a number of seafood products. These organoarsenicals (mainly arsenobetaine and arsenocholine) are relatively nontoxic and are rapidly excreted unchanged. The most common methods for measuring As in urine involve a vigorous acid digestion procedure prior to hydride generation atomic absorption or direct graphite furnace analysis. These methods would measure dietary arsenic as well as inorganic As from occupational exposure. Following a single seafood meal, total As levels as high as 1000 \(\mu g\) L\(^{-1}\) have been observed. Thus measurement of total As in urine as means of assessing As exposure in the presence of dietary As is meaningless. Fortunately, the problem has been overcome by the development of analytical methods which can differentiate between As from the diet and As from occupational exposure. Many different approaches have been used, from direct hydride generation techniques to the extreme of hyphenated technology, high-performance liquid chromatography (HPLC)/hydride generation/photochemical reactor/ICP/AES (inductively coupled plasma atomic emission spectroscopy).

### 11.2 Direct Hydride Reduction Methods

Hydride generation atomic absorption is an ideal method for determining As and inorganic As metabolites. This is due to the fact that As\(^{3+}\), As\(^{5+}\), monomethylarsonic acid (MMA), and DMA all readily produce gaseous hydrides. However, the organic forms of As present in seafood (arsenobetaine and arsenocholine) do not form hydrides directly. Hydride generation AAS provides a method of distinguishing between the inorganic and organic forms. The method involves generation of hydrogen from acid and sodium borohydride which reacts with As\(^{3+}\) to form arsine (AsH\(_3\)), with MMA to produce methylarsine, and with DMA to produce dimethylarsine. The arsine gas formed is directed to a flame-heated quartz tube placed in the light beam of the atomic absorption spectrophotometer. The heat converts AsH\(_3\) to As\(^0\) for subsequent AAS detection.

The formation of the gaseous hydride for each of the As species depends on a number of factors: the acid used, the concentration of the acid, the concentration of the borohydride, the concentration of sodium hydroxide used to prepare and stabilize the borohydride solution, and the design of the hydride generator. The last point is most interesting. There is wide variation in the ability of commercial hydride generation systems to form, for example, arsine from As\(^{3+}\). Continuous flow systems that mix the sample, the acid, and the borohydride in a small chamber just prior to the gas liquid separator (which delivers the arsine gas to the detector and the liquid to waste) discriminate significantly against As\(^{5+}\). Without prereduction of As\(^{5+}\) to As\(^{3+}\), no signal will be observed for As\(^{5+}\). Nonflow systems that allow the reactants to mix together for a period of time prior to release of the gas will give a significant but not equal signal for As\(^{5+}\) compared with As\(^{3+}\). This is due to reduction of the +5 form to the +3 form prior to formation of the hydride. Flow-through systems which include mixing coils of various lengths placed before the gas/liquid separator can improve the response for +5. One group of researchers has studied this reaction in detail with the result that selective reduction can be used to measure many of the forms independently of each other.\(^{(79,80)}\)

In an occupational monitoring setting, the total of the inorganic species, As\(^{3+}\), As\(^{5+}\), MMA, DMA, is most important. By adjusting acid concentrations and borohydride concentrations it is possible to obtain an equal response from each of the four As species. This method has been used for the determination of inorganic As and metabolites in urine.\(^{(81–84)}\) Ion-exchange chromatography using disposable solid-phase extraction columns has been used to separate the inorganic species from the organic prior to hydride generation.\(^{(85)}\) In another method using ion-exchange chromatography, As\(^{3+}, 5^+\), MMA,
and DMA were separated and analyzed individually by hydride generation atomic absorption.\(^{98}\)

### 11.3 Hydride Generation/Low Temperature Separation

Hydride generation/liquid nitrogen trapping/thermal separation is one of the earliest methods known to determine the various As species. In this method, the various forms of As are reduced to their hydrides and trapped in a liquid nitrogen cold trap. The trap is allowed slowly to return to room temperature during which time arsine and the methyliarsines distill off one at a time. Direct current discharge atomic emission and AAS have been used for detection.\(^{87–89}\)

### 11.4 Graphite Furnace Methods

GFAAS has been used for the determination of As in urine. Direct analysis of urine would give total As and be subject to the difficulties mentioned earlier. However, there are cases when total As in urine may be of interest.\(^{90}\) Combining GFAAS with a column chromatographic separation of inorganic and organic forms prior to furnace determination has been used.\(^{91,92}\) The cation-exchange chromatography step separates As\(^{3+}\), As\(^{5+}\), MMA, and DMA from arsenobetaine and other dietary organoarsenicals. Another approach is the combination of solvent extraction and GFAAS.\(^{93,94}\) The method involves extraction of As species from acidified urine following reduction with potassium iodide. Only the As\(^{3+}\), As\(^{5+}\), MMA, and DMA are extracted under these conditions allowing elimination of the other organo arsenicals.

### 11.5 High-performance Liquid Chromatography/ Hydride Generation/Atomic Absorption

In this procedure the As species are separated by HPLC, and the effluent from the column is directed into a continuous hydride generation system with on-line atomic absorption detection. Separation of the As species typically involves anion-exchange chromatography.\(^{95–97}\) Reversed phase ion-pair chromatographic separation on a C\(_{18}\) column has also been used.\(^{98}\) Novel modifications of this method have appeared. Using low-power ultraviolet irradiation after column separation and before hydride generation allows the determination of a number of As species including arsenobetaine and other organoarsenicals.\(^{99}\) The organic As compounds were also separated and determined using thermochemical hydride generation.\(^{100}\)

### 11.6 High-performance Liquid Chromatography/ Hydride Generation/Atomic Fluorescence

HPLC/hydride generation with atomic fluorescence detection has also been applied to As speciation.\(^{101}\) This method has been improved using short-column liquid chromatography to allow separation of the four As species in 3 min.\(^{102}\)

### 11.7 High-performance Liquid Chromatography/ Inductively Coupled Plasma Atomic Emission Spectroscopy

Direct coupling of HPLC to ICP/AES has been used for As speciation.\(^{103}\) HPLC separation by anion- and cation-exchange chromatography was compared. Ion-pairing reversed phase separation has also been used.\(^{104}\) A column-switching valve system was used combining both anion-exchange and reversed phase separation prior to ICP/AES detection.\(^{105}\) An interesting system adds hydride generation and a photoreactor to ICP/AES to improve detection limits.\(^{106}\) In this system the effluent from the column is mixed with photooxidation chemicals, followed by a specially designed photoreactor, followed by the hydride generation system, followed by ICP/AES detection. The system allows detection of the four inorganic As species as well as arsenobetaine and arsenecholine.

### 11.8 High-performance Liquid Chromatography/ Inductively Coupled Plasma Mass Spectrometry

The direct coupling of HPLC and ICP/MS has been used to determine various As compounds in urine.\(^{107}\) By combining anion-exchange and cation-exchange chromatography, the four anionic As species as well as the four cationic species were detected. This arrangement also eliminated the argon chloride interference common in ICP/MS.\(^{108}\) Microbore HPLC and microscale flow injection coupled to ICP/MS allowed sub-parts per billion determination of As species.\(^{109}\)

### 11.9 Dietary Arsenic: Arsenosugars

Unfortunately, the contribution of dietary As cannot be completely eliminated even when As speciation methods are employed. Certain marine animals especially crustacea have the ability to convert organoarsenicals to DMA. The contribution is small (10%) and not significant in occupational exposure but would be of importance when assessing low-level environmental exposure. More significant is the contribution due to ingestion of certain forms of seaweed which have been found to contain high levels of arsenosugars as well as much smaller amounts of DMA and As\(^{5+}\). Arsenic species in various marine organisms have been determined using the techniques mentioned above: arsenosugars and inorganic As compounds by HPLC/ICP/MS.\(^{110}\) HPLC/ICP/MS has been used to study urinary As excretion following ingestion of seaweed, crab, and shrimp.\(^{111}\) In the case
of crab and shrimp virtually all of the As excreted was arsenobetaine. However, in the case of seaweed significant levels of DMA, As$^{5+}$, and three unidentified metabolites were observed. In a recent paper using ion-pair liquid chromatography with hydride generation and atomic fluorescence detection, a substantial increase in urinary DMA was observed following ingestion of seaweed.\textsuperscript{(112)} The authors point out that the commonly used biomarkers of exposure to inorganic As may not be reliable when arsenosugars are ingested.

12 MULTIPLE METALS METHODS

A number of methods for the determination of multiple metals in biological samples have been published. Most of these methods involve ICP/AES or ICP/MS as the detection sources. Two National Institute for Occupational Safety and Health (NIOSH) methods have been published using ICP/AES. One method (NIOSH 8310) involves the determination of 16 metals in urine using a polydithiocarbamate resin extraction technique.\textsuperscript{(113)} The detection limit is about 1 µg L$^{-1}$. For the determination of 20 different metals in whole blood or tissue, NIOSH Method 8005 uses a digestion of blood prior to ICP/AES determination.\textsuperscript{(114)} The detection limit is approximately 10 µg L$^{-1}$ for each metal.

As mentioned earlier, the great sensitivity of ICP/MS coupled with multielement capacity makes this an ideal method for the determination of metals in blood or urine. Review articles by Houk on ICP/MS\textsuperscript{(115)} and, especially, Durrant\textsuperscript{(116)} on ICP/MS in biological analyses provide a detailed look at this most promising technique. Methods for the determination of Cd, Pb, and Hg in whole blood,\textsuperscript{(25)} as well as Al, As, Cd, Pb, and Zn\textsuperscript{(26)} by simple dilution were previously mentioned.

Many other methods have been published using ICP/MS. Only a few of them will be mentioned here: Fe, Co, Cu, Zn, Rb, Mo, and Ce were determined in human serum by a method that involved nitric acid dilution.\textsuperscript{(117)} Interferences from polyatomic ions were corrected by a matrix blank solution. Direct determination after simple dilution of urine with nitric acid was studied by Mulligan et al.\textsuperscript{(118)} A number of metals were studied for detection limit, linearity, and interferences. Detection limits were around 1 µg L$^{-1}$ for most metals. The method was compared to established methods for Sb, Cd, and Hg with good results. A number of interferences were noted in the 10 to 80 mass range. Good stability was observed during continuous working day operation. Vaughan et al. looked at a ten-fold dilution of biological samples and were able to detect 13 metals reliably in serum, 15 metals in whole blood, and 25 elements in saliva.\textsuperscript{(119)}

Mass overlap was a problem for some metals (Cr, Mn, and V) as well as matrix-induced effects. Some of the matrix effects were minimized by using matrix-matched standards and the method of standard addition. Hsiung et al. studied in detail interferences encountered when determining metals in biological samples.\textsuperscript{(120)} Sample preparation involved simple dilution in the case of urine and nitric acid protein precipitation for serum. The importance of selecting the right isotope to minimize polyatomic interferences and the use of external and internal calibration to minimize matrix effects were emphasized. A completely automated method that included all aspects of the analysis from sample preparation to final analysis was published by Huang et al.\textsuperscript{(121)} Sample preparation involved flow-through microwave digestion, followed by on-line resin column extraction to remove matrix interferences, followed by column elution and ICP/MS determination. Elements studied included Fe, Ni, Cu, Zn, and Pb.

Simultaneous multielement GFAAS has been used to determine up to four metals in plasma. Al, Cr, Mn, and Ni were determined in serum and plasma using this technique.\textsuperscript{(122)}

ASV has been applied to the simultaneous determination of Zn, Cd, Pb, and Cu in urine\textsuperscript{(123)} and Cu, Pb, and Cd in whole blood.\textsuperscript{(21)}

13 OTHER METALS

Aluminum: there is no BEI\textsuperscript{™} for aluminum; however, there is a BAT for Al in urine of 200 µg L$^{-1}$. GFAAS has been used to determine Al urine in both plasma and urine.\textsuperscript{(124,140)}

Manganese: the validity of using either blood or urine monitoring to assess Mn exposure is debatable. However, numerous GFAAS methods have been used to measure Mn in biological samples both from a nutritional and an occupational exposure perspective.\textsuperscript{(125–128)}

Nickel: there is no BEI\textsuperscript{™} or BAT. At an air exposure level of 0.10 mg m$^{-3}$, the observed value for Ni in urine is 15 µg L$^{-1}$. The most common method for Ni in urine is GFAAS.\textsuperscript{(129,130)}

Vanadium: there is a BEI\textsuperscript{™} for vanadium pentoxide which is total V in urine of 50 µg g$^{-1}$ creatinine. V in urine can be determined by GFAAS.\textsuperscript{(131,132)}

14 SAMPLE COLLECTION

14.1 Introduction

Sample collection is one of the most important issues in any analytical determination. It is critical to any determination involving trace metal analysis because sample
contamination is always a major concern. The subject has been covered in detail by Aitio and Jarvisalo,133 Sources of potential contamination include the sample collection device (needles for blood collection), sample collection containers, the environment where the sample was collected, and the hands of the person collecting the sample. These considerations, as well as those associated with sample preservation and shipping, must be addressed to insure an unadulterated sample.

14.2 Urine Collection

An accurate 24 h urine sample is the ideal specimen for any determination involving urine. However, this type of sample is not feasible for occupational exposure monitoring. For this reason the ACGIH developed the BEIs, based upon timed spot-urine collections. Samples are typically collected at preshift, postshift at the end of the day, postshift at the end of the week, and so on. The disadvantage of a spot-urine sample is the variation in dilution that occurs due to the variability of hydration of the worker. The most common way to address this variability is to normalize the urine values by using a creatinine correction for each specimen. Creatinine is a normal endogenous constituent in urine. Specific gravity can also be used but there are limits to the effectiveness of this correction factor. The creatinine level should be within the range of $0.5–3\, \text{g}\, \text{L}^{-1}$. Outside this range, the concentration of the appropriate analyte will be overcorrected. For instance, in the case of a dilute urine of $0.2\, \text{g}\, \text{L}^{-1}$, the uncorrected concentration will be multiplied by a factor of five often resulting in a falsely elevated result. To avoid erroneous results, one approach is to check the specific gravity at the site of collection with a urine test strip. If the urine specific gravity is greater than 1.015, the creatinine is usually greater than $0.5\, \text{g}\, \text{L}^{-1}$. This will avoid inconsistent results and retesting. The calculated value is obtained by dividing the analyte value in milligrams per liter (or micrograms per liter) by the creatinine value which is in grams per liter to obtain a value of milligrams per gram (or micrograms per gram) of creatinine.

Urine samples are collected in plastic cups or bottles that have been acid washed or have been analyzed to insure that they are free of trace metals. Preservation of urine samples for trace metals usually involves acidification with dilute acid. To avoid the possibility of contamination, acidification should never be done in the field. One way to avoid this situation is to send the samples to the laboratory, refrigerated by overnight courier, and to acidify the samples at the laboratory. Another approach is for the laboratory to provide two containers, a wide-mouth acid-washed container for sample collection and a leak-proof transport bottle containing an acid preservative for shipping. Samples should be surrounded by cold packs in a cooler that meets the regulations covering the shipping of biological samples. Samples should be sent to the laboratory by next day or second day delivery.

14.3 Blood Samples

The most convenient way of collecting a blood sample for the determination of trace metals in blood is the use of an evacuated tube, Vacutainer®, Venoject®, and so on. While convenient, these tubes are known to be potential sources of contamination for a number of metals, particularly aluminum and zinc. For metals such as Pb, Cd, Hg, and As, contamination is not an issue. Evacuated tubes containing ethylenediaminetetraacetic acid (EDTA) as an anticoagulant are routinely used, for example Purple top Vacutainer® EDTA binds with the calcium in the blood sample and interferes with the clotting process. This provides a longer anticoagulant action than heparin and is recommended when there is a delay between the sample collection and the analysis. Stability is not an issue for these metals, although samples should always be shipped in insulated containers to avoid temperature extremes that could result in an aesthetically displeasing sample. Note that temperature extremes can have a significant effect on ZPP determinations often collected along with blood lead.

For metals such as Al, Co, Cr, Ni, and Mn extreme caution must be taken to avoid contamination in all aspects of the sample collection process. Glass Vacutainer® tubes should not be used for these metals. Plastic Vacutainer® tubes have been found to be virtually free of metals contamination and are recommended for exposure monitoring for these metals. However, for nutritional monitoring purpose these tubes may not be acceptable for all metals. The reader is referred to the National Committee for Clinical Laboratory Standards (NCCLS) document on this subject.134 Contamination of the blood sample with metals from stainless steel needles is also an issue of concern.135 For occupational exposure purposes flushing of the needle by taking a preliminary blood sample before the actual trace metal sample is taken can be effective in limiting contamination from the needle.

For determinations requiring plasma or serum, an additional source of contamination must be considered. After collection in an appropriate tube, the sample is centrifuged and the plasma/serum layer transferred to another tube. This step must be performed using a plastic transfer pipette and a plastic tube known to be metal free in a laboratory environment. It should not be attempted in the field. Glass transfer pipettes and glass tubes should never be used.

All containers, evacuated tubes, transfer pipettes, transport tubes, and so on should be checked on a regular...
basis for metal contamination. This is accomplished by analyzing several samples from each manufacturers’ lot of materials.

15 QUALITY CONTROL/QUALITY ASSURANCE

QC and quality assurance (QA) are an essential part of any analytical determination no matter what matrix is being analyzed or which chemical is being measured. Every laboratory must have a formal QA/QC program in place to insure the validity of their data. This is true for all laboratories performing biological monitoring analyses. There are a number of preanalytical and analytical parameters involved in every determination. While a presentation on QA/QC is not the purpose here, two preanalytical QA parameters and two analytical QC parameters that affect biological monitoring should be mentioned. The subject of QA/QC in biological monitoring has been dealt with in previous publications. Preanalytical parameters include laboratory certification and proficiency testing. All laboratory testing falls under the jurisdiction of some certifying or accrediting organization. The same is true of laboratories performing biological monitoring.

For example, in the USA biological monitoring laboratories fall under the CLIA’88. Any laboratory analyzing biological samples must obtain a CLIA certificate. Laboratories performing biological monitoring analyses will require a high-complexity testing certificate. Laboratories can be accredited by the CAP, by individual states, or by any other accrediting agency approved by CLIA. In addition, laboratories must be

The two preanalytical parameters of great interest to biological monitoring laboratories are calibration standards and QC materials. Calibration Standards are important since quantitative determinations are only as accurate as the Standard on which they are based. In the area of trace metal determinations, the NIST provides 67 different SRMs consisting of individual certified metal standard solutions which are used as primary metal standards. In addition, standard solutions of most metals are available from a number of manufacturers at various concentrations which are certified against these NIST SRMs. NIST also provides a blood-lead standard SRM (955b) consisting of four whole-blood calibrators which can be used as calibration standards or QC samples. Calibration verification standards are also available from a number of sources, all NIST traceable.

Matrix-matched QC materials provide the best means of assessing the overall accuracy of a biological monitoring determination and should be included in every analytical run. For the determination of trace metals in blood/urine/serum/plasma, a number of QC materials are available. Table 6 lists those materials available from NIST. In addition to the NIST blood-lead standards/controls mentioned earlier, urine-based standards/controls are available for a number of metals and fluoride. NIST materials are the gold standard and can be used with confidence. The bilevel controls include a normal control and an elevated control. For any other level, the elevated control can be diluted with the normal control to obtain the desired concentration. Tables 7–10 list many of the various commercial QCs that are available for blood lead, urine metals, whole-blood metals, and serum metals, respectively. These controls are also bilevel including a normal and elevated level.

Matrix spike analysis is a valuable method for checking the accuracy of any analytical method. This is especially true in cases were matrix-matched QC materials are not available. A matrix spike is a sample to which a known amount of the analyte of interest is added. The original sample and this spiked sample are then analyzed.

The difference should correspond to the amount spiked. Acceptable recovery ranges from 75 to 125% in most cases. Spiking should be done at two or three different concentration levels. While 10% spikes is normal, for highly critical analyses it is not unusual to perform 20% spikes (every fifth sample).

16 THE FUTURE

Biological monitoring will continue to provide new information about metal exposure and enable us to protect the health of workers better. Analytical chemistry will have an important role in this effort. Analytical methods are improving daily with lower levels of detection coupled with good accuracy and precision. Analytical methods like ICP/MS which combines graphite furnace detection limits with multielement capability will find wider application. In addition, advances in automation and computer control will make ICP/MS instrumentation easier to use, more reliable, and more cost effective. GFAAS instrumentation continues to improve. Systems are now faster, more reliable, and at lower cost.

One particularly exciting aspect of trace metal analyses has already been mentioned. This is the area of metal speciation. Speciation methods were discussed for arsenic and mercury but are applicable to many other metals. Considerable work has been done in the area of trace metals of nutritional importance, for example selenium and chromium. These methods all combine a chromatographic separation technique, such as HPLC, with an elemental detection technique, such as ICP/MS. These studies will be expanded to the toxicologically important metals as well. A publication dealing with the various aspects of trace metal speciation has appeared. (139)

The biochemistry of trace metals has always been and will always be an exciting and active field.

1 Introduction

Neutron radiography (NR) can be used to quantify the spatial distribution of water in the soil–plant system with high precision and good spatial resolution. This property of neutron imaging results from the high interaction probability of hydrogen nuclei with slow neutrons. If there is a sufficient difference between the water content of the soil and roots, neutron radiographs can reveal plant roots and show root development. NR is noninvasive, and the radiation dose needed to image plant roots in soil does not affect plant development. Quantification of the soil's water content often requires correction for neutron-scattering artifacts. Root visibility is proportional to root thickness, and is inversely related to the width of the sample container and the water and organic matter contents of the ambient soil. Ideally, the soil should have low organic matter content and low water content but still permit the normal development of plant roots. Currently, the availability of neutron-imaging facilities limits the widespread application of NR to soil and root studies. However, technological development and increased investment will result in NR becoming a standard method for some soil–plant analyses.

1 INTRODUCTION

Terrestrial plants provide humanity with food and oxygen. Above- and belowground plant processes are equally important: while assimilation through photosynthesis occurs in the aboveground portions, the uptake of water and mineral nutrients occurs belowground. We have a limited understanding of some belowground processes because soil hinders the observation of plant roots. It is difficult to measure root development and water flux in the root zone without disturbing root growth or using artificial systems. Existing techniques include minirhizotrons, which are transparent plastic tubes inserted into the ground to view the roots, e.g. by using a video camera. Minirhizotrons interfere with the root environment and only provide an incomplete picture. X-ray radiography has insufficient contrast to reveal root–water interactions.

Willatt et al. showed that NR could reveal roots and root zone processes, without greatly perturbing the system, thus allowing sequential measurements. This is a critical advantage of NR over other techniques. However, the available technology in the 1970s gave images of insufficient quality and exposed the plants to radiation doses that were potentially harmful. Recent technological developments, especially improved beam collimation, detection systems, and image-processing techniques, have allowed the production of images with much higher contrast and spatial resolution while reducing the plants' radiation exposure. These advances open up the possibility of using this technique to study root system development in soils and simultaneously monitor soil moisture distribution in near real time. Here, we describe the state of the art of NR as it relates to the analysis of plant–soil interactions.
down using a moderator such as heavy water. Neutrons enter a collimator that forms a neutron beam with specific geometric properties. The collimator may also contain filters that modify the energy spectrum of the beam or reduce the beam’s content of γ rays. The neutron beam is transmitted through the sample onto a plane position-sensitive detector, which is usually a scintillation screen. A charge-coupled device (CCD) camera coupled to the detector records a two-dimensional image that is a projection of the object on the detector plane. The advent of high-resolution digital cameras has allowed fast imaging and increased resolution. Digital imaging techniques that use a CCD camera combined with image-processing tools nowadays yield quantifiable images with a resolution of about 100 µm. Lehmann et al. obtained a much higher spatial resolution with a special setup for microtomography. The required exposure time for such images is in the order of seconds. Images acquired using imaging plates or films (used until 1995) required several minutes of exposure to the potentially damaging neutron beam. The radiation dose received per image using modern techniques is about 0.003 mSv, which is some two orders of magnitude less than the minimum value of 0.2 mSv h⁻¹ found to affect plant growth.

3 NEUTRON INTERACTIONS WITH THE PLANT–SOIL SYSTEM

NR is based on the Beer–Lambert exponential law of attenuation of radiation passing through matter:\(^{(7)}\):

\[ I = I_0 \exp(-\Sigma \text{sample} \cdot d) \]  

(1)

where \( I \) is the attenuated radiation (neutron) flux (cm⁻² s⁻¹), after an incident neutron flux \( I_0 \) passes through a material of thickness \( d \) (cm) with an attenuating coefficient \( \Sigma \) (cm⁻¹), which is a characteristic of the material. The attenuation coefficient, also called the macroscopic cross section, is related to the tabulated microscopic cross section \( \sigma \) (cm²) as

\[ \Sigma = N \sigma \]  

(2)

with a nuclear density \( N \) (M). When a sample is placed in a neutron beam, heterogeneities in the composition and thickness of the sample result in variations in the intensity of the transmitted beam. Unlike X rays, neutron radiation interacts with atomic nuclei. There is no systematic change in the neutron attenuation coefficient with atomic number or mass. Each isotope has a specific neutron cross section, \( \sigma \), which is also energy dependent. Hydrogen has a neutron cross section some 10 times greater than deuterium and also greater than many other elements in the soil–plant system.

NR reveals structures in plant–soil systems owing to differences in the \( \Sigma \) values of the system’s components. Table 1 shows a list of the chemical elements in the plant–soil system, along with their abundances and relative neutron cross sections. In both plant and soil, hydrogen is responsible for more than 90% of the neutron attenuation.

Some hydrogen is associated with organic molecules in the system; however, most hydrogen is water borne. Plant roots may thus be distinguished from soil due to their higher water content (\( \theta \)). The gravimetric water content, \( \theta \) (g g⁻¹) of plant roots generally ranges between 0.7 and 0.95 g g⁻¹, while that of soils at field capacity usually ranges between 0.12 and 0.3 g g⁻¹. The structures that NR reveals in the soil–plant system are sensitive to \( \theta \).

The high neutron attenuation coefficient of hydrogen is an important advantage of NR over X rays when applied to soil–plant system because the difference in water content allows the visualization of roots. The X-ray attenuation coefficients of root and soil components are less distinct (data not shown); therefore, the resulting radiograph has less contrast. Figure 2 shows that NR provides a better contrast between roots and soil than X rays.

The attenuation coefficient (\( \Sigma \)) results from two types of neutron interactions with matter: absorption (\( \Sigma_a \)) and scattering (\( \Sigma_s \)) (Figure 3a). Hydrogen attenuates neutrons primarily by noncoherent elastic scattering.\(^{[11]}\) Neutron scattering causes deviations from the exponential law of attenuation for thicker samples (more than a few millimeters) because some neutrons are multiple scattered into the detector plane, thus producing
Table 1  Chemical elements, listed in order of abundance, in the plant–soil system, along with their relative neutron attenuation coefficients. The plant and soil are assumed to have water contents of 0.8 and 0.2 g g\(^{-1}\), respectively.

Figure 2  Comparison of contrast between roots and soil in X-ray (120keV) radiograph (a) and neutron radiograph (b) of the same sample. While soil heterogeneity and soil cracks are more visible in the X-ray radiograph, neutron radiography provides better contrast between soil and roots.

Figure 3  Comparison of neutron attenuation properties for different chemical elements. Elements such as Hydrogen (H), Oxygen (O), Silicon (Si), Carbon (C), Aluminum (Al), Potassium (K), Nitrogen (N), Calcium (Ca), Iron (Fe), Magnesium (Mg), Phosphorus (P), Sodium (Na), Chlorine (Cl), Molybdenum (Mo), and Manganese (Mn) have high neutron attenuation properties. Elements such as Zinc (Zn), Boron (B), Copper (Cu), and Boron (B) have low neutron attenuation properties.

4 CONFIGURATION OF SOIL–PLANT SYSTEM FOR OPTIMAL IMAGING WITH NEUTRON RADIOGRAPHY

A neutron radiograph is the result of all the neutron attenuation processes that occur when the neutron beam passes through a sample. The \(\Sigma\) value of the soil depends on \(\theta\) and the neutron attenuation properties of its solid components. Soils that are high in iron or organic matter...
are unsuitable for NR because their high $\Sigma$ values obscure the visualization of plant roots. The value of $\theta$ of the soil at the time of measurement should be as low as possible without inducing water stress in the plants. In practice, this represents the soil’s $\theta$ at a water potential of $-1$ bar. Silica sands have a low inherent $\Sigma$ and a low $\theta$ at $-1$ bar. However, Menon et al.\textsuperscript{5) showed that the high density and sharp edges of this material perturb normal root growth. Moradi et al. (unpublished data) tested a variety of plant growth media for their suitability in NR (Table 2).

Table 2 shows that loamy sand, which permits normal root development, has a relatively low $\Sigma$ at a $\theta$ at a water potential of $-1$ bar. Loamy sand has a higher $\theta$ at field capacity (ca. 0.35 g g$^{-1}$) than quartz sand (ca. 0.15 g g$^{-1}$). Plants can thus be left longer in loamy sand without irrigation.

Root visibility is proportional to root thickness, and inversely related to the width of the sample container.\textsuperscript{13–17) The minimum detectable root thickness increases exponentially as the thickness of the soil profile increases. Moradi et al. (unpublished data) showed that using the loamy sand in Table 2, with a soil $\theta$ of 0.16 g g$^{-1}$ (ca. $-1$ bar) and an average root $\theta$ of 0.85 g g$^{-1}$, the minimum detectable root thickness $R$ (mm) is related empirically to the slab thickness $T$ (mm) according to the function:

$$R = 0.0034T^{-1.68}$$ (3)
Roots are most easily visualized in thin containers. However, this condition is not conducive to plant growth since the walls of the container restrict root development. Therefore, one needs to find a balance between the ease of root visualization and the restriction of normal plant development.

For many herbaceous species, a soil profile with a thickness of 12 mm provides enough space for relatively normal root development. This gives a minimal detectable root thickness of 0.22 mm (Equation 2). Such a setup allows the visualization of the skeleton of the root system; however, fine roots (<2 mm in diameter) are undetectable.

5 PRACTICAL CONSIDERATIONS

The sample container should be made of a material with a low $\Sigma$, such as aluminum ($\Sigma = 0.1 \text{ cm}^{-1}$). Importantly, the system should not contain high concentrations of cobalt, which can form the persistent radioactive isotope Cobalt-60, with a half-life of about five years, upon exposure to neutron radiation.

Filling the sample container with soil as homogeneously as possible provides better contrast for root visualization. Filling from the side of the container rather than from the top results in less structural heterogeneity associated with variations in the particle size distribution and thus pore size distribution, which are visible in the resulting neutron radiograph because of variations in soil water content. Figure 4 shows the effect of filling patterns caused by pouring soil from the top of the container.

The suitability of NR to investigate root systems differs among plant species. As described earlier, thick roots with a high $\theta$ are more easily resolved than finer, drier roots. In a 10-mm-thick soil profile, the minimum detectable root size is ca. 0.16 mm (Equation 2). However, many plant species produce finer roots, which would not be visible in this system. Decreasing the thickness of the soil profile may permit the visualization of these roots, but may cause unnatural root growth patterns due to confinement. Moradi et al. (unpublished data) reported good root visibility in some members of the Fabaceae and Asteraceae families, whereas resolution was insufficient in Brassicaceae, Solonaceae, and Poaceae. In principle, larger species such as small trees could be investigated using NR. However, this would require a larger container for nonperturbed growth. Consequently, the spatial resolution would decrease and one could only resolve large structural roots.

The water content of the soil and the plant should be monitored so that the soil water content is low enough at the time of imaging to provide adequate contrast yet not so low that the plant becomes water stressed. If a series of measurements are to be taken, then one can calculate the soil $\theta$ in the zone of interest from the results of each radiograph. This requires scattering correction and a water quantification algorithm calibrated for the particular plant–soil system. Water quantification using NR has the advantage over a gravimetric measurement because it can be used to determine the water content of the soil in the zone of interest, rather than providing an average value of a soil profile that may have a heterogeneous moisture distribution.

The neutron beam formed in the collimator is not perfectly homogeneous. This also holds for the detector system. Therefore, there are spatial variations in intensity of the resulting radiography that are caused by the beam, rather than the sample. This requires that each radiograph be corrected by normalizing the image by a “flat field” or open-beam image with no sample. Similarly, noise generated by the camera assembly should be removed. A

![Figure 4](https://example.com/figure4.png)

**Figure 4** Soil heterogeneity resulting from filling patterns can affect the image quality. The radiographs show the roots of *Cicer arietinum* in identical soil with high heterogeneity (a) and low heterogeneity (b).
6 APPLICATION

The application of NR can enhance the study of root development and root–soil interactions by revealing the location of roots over time without disturbance. Plant root development is a function of the plant species and the nature of the soil into which they penetrate. Soil components, such as organic matter, nutrients, and contaminants, occur heterogeneously. NR is an ideal tool to study how roots interact with patches of low or high concentration. When roots encounter a patch or discontinuity in soil, they may proliferate, wither, or continue growing unaffected. Figure 5(a) and (b) shows how NR can reveal plant responses to a patch of nickel, a toxic heavy metal, in soil. Such experiments, for example, may reveal species that avoid contaminant hotspots and reduce the risk of plant contaminant uptake. Similarly, understanding the mechanisms by which crop plants interact with patches of nutrients may aid the development of treatments to improve crop, and subsequently human, nutrition.

Perhaps more importantly, NR can quantify the spatial distribution and flux of water in the plant–soil system in near real time, in combination with root imaging. This permits the study of root water uptake and the effect of roots on the passage of water through soil. Figure 6 shows a series of images detailing water infiltration into a profile and water uptake by plant roots. Such studies have a wide variety of potential applications, such as selecting vegetation to minimize leaching from contaminated sites and the optimization of irrigation and fertilization systems.

7 CONCLUSIONS AND OUTLOOK

The quantification of root mass and soil water content using NR of plant–soil interactions has considerable scope for improvement, particularly, the processing of raw images obtained at the neutron facility. Refinement of root segmentation algorithms described by Menon et al. would greatly enhance the accuracy and precision of the technique. One obvious drawback of NR is that, at present, it requires access to a specialized facility, of which there are only a few available worldwide with the desirable performance. Competition for beam time is fierce, since NR finds applications in many fields of science. However, the usefulness of NR indicates that it may follow the same pattern of development as synchrotron radiation facilities. Initially, financial

Figure 5 Neutron radiographs of two 150 mm × 150 mm × 120 mm slabs filled with sandy loam. The area to the right of the dotted line was spiked with 125 mg kg⁻¹ Ni. The roots of *Cicer arietinum* (b) avoid the high-Ni zone, while the roots of *Berkheya coddii* (a) are unaffected. Neither plant showed any differences in the aboveground portions relative to their respective controls.
Figure 6  The change in water content (both positive and negative) of a 150 mm × 150 mm × 120 mm container, in which *Lupinus albus* was growing, after the infiltration of 10 mL of water ((a) 1–2 min, (b) 2–5 min, (c) 28–40 min). The wet front shows up as a dark band, while root water uptake is visible in b and c as a discontinuous gray area.

and technical constraints limited their application, but their usefulness ensured subsequent technological development and capital injection, and thus they became commonplace and the standard equipment for some analyses.

1 INTRODUCTION: ROLE OF NUCLEAR REACTION ANALYSIS IN COMPARISON WITH OTHER ION BEAM ANALYSIS TECHNIQUES

When a material is irradiated with charged particles like protons, deuterons, α-particles or other heavier ions, at energies ranging from a few hundred kiloelectron volts to a few meaelectron volts, the emission of photons, charged particles and neutrons gives rise to various spectroscopic methods of elemental analysis. The great majority of interactions of the incident charged particles with atoms of the irradiated material take place with atomic electrons: the incident particle progressively loses its energy (−dE) in the material. The energy loss dE is expressed by Bethe’s law of stopping power S(E) Equation (1):

$$S(E) = - \frac{\frac{dE}{dx}}{\rho} = K \frac{z^2 m Z}{\rho\ln a E} \frac{m A}{E_i}$$

where z, m and Eᵢ are respectively the charge, mass and the energy of the incident particle, where ρ, I, Z and A, are respectively the density, mean ionization potential, atomic number and the atomic mass of the material, and a is an adjustable parameter. K comprises only physical constants. When the incident particle has sufficient energy to ionize atoms from any shell, S(E) decreases with the increase in the incident energy (Table 1). Exceptions to this general rule occur at low incident particle energy, as seen for He⁴ and He³ ions in Table 1, when the projectile cannot eject inner shell electrons, the main consequence being that Zₑff < Z. Therefore S(E), in those cases, is smaller than the expected value.

The incident particle comes to rest after crossing a distance R, known as the range. This incident particle does not experience an appreciable deviation when interacting with atomic electrons. Interaction with one atomic nucleus only rarely causes deviation of the incident particle from a straight line. The range is almost the total distance that the particle travels following a straight line in the material. The range (R) increases with the incident projectile energy (R ~ Eᵢ), and decreases with an increase in its charge and its mass. Table 2 gives some data on ranges of protons, deuterons,³He and α-particles (R) for a selection of light, medium and high Z elements.

Note that the particle range increases with the atomic weight of the material owing to a dependence on Z/A.

During this slowing down of the projectile, a statistical transfer of energy to the atomic electrons of the material takes place. This statistical behavior of the energy loss of the projectile gives rise to energy straggling: an unequal energy loss from identical particles crossing the same target material under identical conditions. The relation between the energy loss and the achieved depth is therefore subject to some inaccuracy. For a very small energy loss, straggling can be calculated using the Landau and Vavilov theory. Energy straggling is not symmetrical around the average value. For monoenergetic protons of 1 MeV crossing a thickness of 2.4 × 10⁻⁵ g cm⁻² (≈90 nm) of pure Al, the mean energy loss is 4.2 keV and straggling on this energy loss has a width at half maximum of 2.7 keV (Figure 1a). For 10⁻³ g cm⁻², the energy loss of 1 MeV protons is 400 keV and straggling gives rise to a Gaussian distribution with a width at half maximum of 27 keV (Figure 1b). The relation between energy and depth achieved in a material is then defined in this case with an accuracy of 7%, which is relatively much lower than the inaccuracy at low incident energy: the greater the energy loss, the smaller the statistical uncertainty in the relation between depth with respect to loss. In most practical cases achievable by NRA, the depth profiling analysis is limited to regions of a few hundred nanometers, where the Landau and Vavilov calculation theory is valid, to a few micrometers where the Gaussian profile is effective. In this last case, the straggling, δ, is simply given by Equation (2):

\[ \delta = 0.93z\sqrt{\frac{Z}{A}}\sqrt{x} \]  

(2)

where x is the depth achieved in μm, z is the atomic number of the incident particle, Z and A are the atomic number and the atomic weight of the target, respectively, and \( \delta \) is the depth achieved in microns.

**Figure 1** Energy straggling of 1 MeV protons for an energy loss of 4.2 keV (a) and 400 keV (b) after crossing a thickness of 2.4 × 10\(^{-3}\) g cm\(^{-2}\) (a) or 2 × 10\(^{-3}\) g cm\(^{-2}\) (b) in Al. (Adapted from G. Deconninck,\(^2\) page 72.)
totally included in the value of \( x \). For compound materials, \( Z \) and \( A \) are simply replaced by the mean values of \( Z \) and \( A \).

The interaction of the incident particle with the atomic electrons of the target induces ionization. When ionization takes place in an inner electronic shell, subsequent rearrangement in order to return to atomic equilibrium leads to the emission of characteristic X-rays: the analytical technique based on this atomic process is called PIXE (particle-induced X-ray emission) (see PIXE (Particle-induced X-ray Emission)). PIXE is a very sensitive method for bulk and trace analysis of elements with an atomic number \( Z \) greater than 20.\(^{(5)}\) PIXE may be also used to study elements from Na to K, but the absorption of low energy characteristic X-rays (1–3 keV) from these light elements into thick samples generally restricts the potential of the method. Analysis of low \( Z \) elements would then only be satisfactory for thin samples or to probe these elements in a very narrow layer at the surface of a bulk material.

When the incident particle passes close to the atomic nucleus, it may be elastically scattered. At very low impact parameter, a particle of mass \( m \) lower than the mass, \( M \), of the collided nucleus, is scattered at an angle close to 180°. The spectroscopy of this backscattered particle (RBS) may easily be used for depth profiling of elements up to thicknesses close to 30% of their own range. The energy of the scattered particle at an angle close to 180° is related to the mass of the collided nucleus, Equation (3)

\[
E_{\text{scatt}} = \left( \frac{M - m}{M + m} \right)^2 E_i
\]  

and to the depth in the material at which the scattering took place. This depth can be determined using the stopping power of the target material. Furthermore, as the cross-section for such elastic scattering is proportional to the \( Z^2 \) of the target atoms, RBS is particularly powerful for the study of high \( Z \) elements (see Rutherford Backscattering Spectroscopy).

The probability of coulomb excitation of a target nucleus leading to the emission of a characteristic \( \gamma \)-rays\(^{(6)}\) is much lower than for the backscattering and inner shell ionization phenomena. Consequently, PIGE (particle-induced \( \gamma \)-ray emission) is of particular interest for the study of light elements (see Particle-induced \( \gamma \)-Ray Emission) where PIXE and RBS suffer from a lack of sensitivity and accuracy. For these light target elements, the characteristic X-rays are of such low energy that they are absorbed into the material itself and RBS offers a much lower cross-section (because it is proportional to \( Z^2 \)). When using heavy projectiles, the forward elastic scattering of light target nuclei give rise to another method of analysis called ERD (see Elastic Recoil Detection Analysis). If the energy of the incident particle is maintained below 5–10 MeV, no delayed radioactivity may be induced as would be the case in CPAA (charged particle activation analysis) typically performed at incident energies greater than 10 MeV (see Charged Particle Activation Analysis). By using all these analytical techniques simultaneously (or sequentially), powerful characterization of many materials may be achieved. In sections 5.3 and 5.6 of this article, we will discuss several complementary applications of nuclear reactions with other ion beam analysis (IBA) techniques.

2 FUNDAMENTALS OF NUCLEAR REACTIONS

In discussing NRA we will concentrate on prompt reactions leading to a transmutation of the target atom and then excluding RBS (see Rutherford Backscattering Spectroscopy), ERD (see Elastic Recoil Detection Analysis) and part of PIGE (see Particle-induced \( \gamma \)-Ray Emission) where the target nucleus does not change during the interaction. We will also exclude delayed \( \gamma \)-ray emission from a transmuted nucleus (see Charged Particle Activation Analysis).

The concise form of a nuclear reaction as expressed by nuclear physicists is

\[
A(a, bc)B
\]

where \( A \) is the target nucleus, \( a \) the incident projectile, \( b \) (and possibly \( c \)) the emitted particles or photons, \( B \) the residual nucleus which is generally a heavy particle carrying a very low energy which remains in the target material and cannot be detected.

In this respect, a reaction named

\[
^{27}\text{Al}(p, \gamma)^{28}\text{Si}
\]

would represent the capture of a proton in an \( ^{27}\text{Al} \) nucleus leading to the formation of an excited \( ^{28}\text{Si} \) which immediately decays to a stable \( ^{28}\text{Si} \) by the emission of a cascade of \( \gamma \)-rays. The spectroscopy of these \( \gamma \)-rays may be used as analytical signals.

The reaction

\[
^{15}\text{N}(p, \alpha\gamma)^{12}\text{C}
\]

would be induced by protons on \( ^{15}\text{N} \) leading to the production of a \( ^{12}\text{C} \) nucleus in an excited state after the emission of an \( \alpha \)-particle. The spectroscopy of these \( \gamma \)-rays emitted by the excited \( ^{12}\text{C} \) or/and the spectroscopy of the emitted \( \alpha \)-particle could be used for analytical purposes.
NUCLEAR REACTION ANALYSIS

The interactions of a loosely bound compound projectile (such as a deuteron) give rise to the emission of energetic protons or neutrons after stripping of the incident deuteron. The breakdown of the incident deuteron (stripping reaction) may be written as

\[ ^{12}\text{C}(d, p_0)^{13}\text{C} \quad \text{or} \quad ^{12}\text{C}(d, p_j)^{13}\text{C}^* \]

The former represents the stripping of an incident deuteron by a \(^{12}\text{C}\) nucleus, leading to the capture of a neutron in \(^{12}\text{C}\) to produce a \(^{13}\text{C}\) nucleus in its fundamental state. The emitted proton has a maximum energy \(E(p_0)\). Various other ways could leave the residual nucleus of \(^{13}\text{C}\) in one of its \((i = 1, 2, 3, \ldots )\) excited states. The corresponding energies \(E(p_i)\) of the \(p_i\) protons are then lower than \(E(p_0)\). The stored energy in the excited \(^{13}\text{C}\) nuclei will shortly afterwards appear as a cascade of characteristic \(\gamma\)-rays of this residual nucleus of \(^{13}\text{C}\). The energy of the emitted protons \(p_0, p_1, p_2, p_3, \ldots \) is quantized and the differences in their energies corresponds to the various quantum states of the residual nucleus. Several groups of protons of different energies, as well as \(\gamma\)-rays, may be used for analytical purposes. Stripping of a deuteron with the capture of the proton is also possible. A neutron is then emitted, but in practice the spectroscopy of these emitted neutrons is much less easy than the spectroscopy of charged particles or photons, so its use in NRA is very limited.

3 KINEMATICS OF NUCLEAR REACTIONS

A fundamental parameter of a nuclear reaction is the \(Q\) value. It represents the balance between the total rest mass of interacting particles and those of emitted ones. Equation (4):

\[ Q = (m_A + m_a - m_B - m_b)c^2 \]  

where \(c\) is the velocity of light in vacuum. A positive \(Q\) value is a characteristic of a nuclear reaction in which some mass is converted into kinetic energy of emitted particles. This \(Q\) value added to the incident particle energy \(E_a\) is shared by both outgoing particles \(B\) and \(b\), Equation (5):

\[ Q = E_b + E_B - E_a \]  

The partition between \(E_B\) and \(E_b\) may be calculated by using conservation laws: conservation of total momentum because the interaction takes place without any influence of external forces; conservation of total mass–energy because the isolated system formed by the incident particle and the target nucleus is being considered. In terms of \(E_a\) and \(E_b\), one finds Equation (6):

\[ Q = E_b \left( 1 + \frac{m_b}{m_B} - E_a 1 - \frac{m_a}{m_B} \right) - \frac{2}{m_B} \left[ E_a E_b (m_a m_b)^{1/2} \right]^{1/2} \cos \theta \]  

When \(b\) is the lightest emitted particle, its energy \(E_b\) in the direction \(\theta\) relative to the incident beam of particles \(a\) is given by Equation (7):

\[ E_b^{1/2} = \frac{\cos \theta (m_b m_a E_a)^{1/2} \pm (m_a m_b E_a \cos^2 \theta)}{m_b + m_b} \]  

As \(E_b^{1/2}\) must be a positive quantity, the plus sign must only be kept if the following condition is met:

\[ (m_B + m_b)m_B Q + (m_B - m_b)E_a| > 0 \]

This is always the case for positive \(Q\) values. For negative \(Q\) values, the minimum \(E_a\) energy giving rise to the emission of \(b\) at \(\theta = 0^\circ\) is given by Equation (8):

\[ E_{a\min} = \frac{m_b + m_b}{m_B + m_b - m_a} \]  

For higher \(E_a\) energies, two different energies may be attributed to the same particle \(b\) emitted at the same angle \(\theta\) but in a limited energy range of \(E_a\) and only for the ejection of \(b\) in the forward direction. We will ignore this special behavior which could be inconvenient for elemental analysis.

A list of selected reactions for the study of light isotopes \((A \leq 20)\) is given in Table 3. Resonant reactions which may be used for depth profiling (see sections 5.1 and 5.2 below) are particularly interesting and a suggestion for the best \(E_a\) incident energies is given.

For hydrogen, helium and lithium isotopes in a material, the detection of coincidental \(b\) and \(B\) particles may sometimes be used to solve chemical interference problems (superposition of signals from particles emitted with the same energy but arising from different \(B\) nuclei). As \(E_b\) energies are also dependent on the emission angle \(\theta\), a specific geometrical assembly may be required for solving interference problems.

The geometry of a nuclear reaction used for analysis in thick target materials is given in Figure 2. The incident particle “\(a\)” hits the sample at point \(I\), crosses a thickness \(x/cos \alpha_a\), losing some of its energy (mainly by interaction with atomic shell electrons) and induces a nuclear reaction at \(P\). The emitted particle with an energy \(E_b(\theta)\) to be calculated for \(E_a = E_a(0) - \Delta E(x/cos \alpha_a)\) is produced at \(P\) and has to cross the distance \(x/cos \alpha_a\) before emerging from the sample surface at \(O\). The outgoing energy at \(O\) is equal to \(E_b(\theta) - \Delta E_b (x/cos \alpha_a)\).

* For applications of these nuclear reactions to elemental analysis see Demortier.\(^{60}\)

The angle $\theta$ is simply $\alpha_i + \alpha_o$. As the most intense fraction of the emitted particles are elastically scattered a particles (see Rutherford Backscattering Spectroscopy), some calibrated absorber has to be inserted between the surface sample and the detector in order to stop them all and then to accept only b particles induced by a true nuclear reaction, when the target nucleus A is transmuted to another one, B. Reactions with large $Q$ values and detection of b particles of mass lower than the mass of a are particularly useful characteristics of nuclear reactions suitable for analysis. A thin absorber will stop all the scattered a particles but will not greatly affect the energy of the lighter emitted b particles (see Equation 1).

In special cases corresponding to a large $Q$ value and a low $E_a$ energy, one may expect to detect b particles selectively with a higher mass than the incident particle a even after crossing the dedicated absorber. Reactions $^6$Li(d,α)$^4$He, $^7$Li(p,α)$^4$He, $^9$Be($^3$He,α)$^8$Be, $^{10}$B(d,α)$^8$Be,
NUCLEAR REACTION ANALYSIS

\[ E_{ap} = E_{a0} - \Delta E(X,\alpha_i) \]

\[ E_{b(\theta)} - \Delta E_b(X,\alpha_o) = E_{b(\theta)} \]

\[ \alpha_o + \alpha_i = \theta \]

Figure 2 Parameters involved in the study of thick materials by the nuclear reaction \( A(a, b)B \).

\( ^{14}\text{N}(d,\alpha)^{12}\text{C} \), and \( ^{19}\text{F}(p,\alpha)^{16}\text{O} \) shown in Table 3 would offer this possibility for an incident \( E_a \) energy in the region of 1 MeV, as would \( ^{11}\text{B}(p,\alpha)^{8}\text{Be} \), \( ^{18}\text{O}(p,\alpha)^{15}\text{N} \), \( ^{19}\text{F}(p,\alpha)^{16}\text{O} \), when using incident protons in the range of a few hundred kiloelectron volts.

The energetic scale of the compound nucleus \( C^* \) made up with all the nucleons of \( A \) and \( a \) (and then also \( B \) and \( b \)) may be represented schematically (Figure 3).

Quantum states have their own energy width \( \Gamma = \Delta E \) (and their associated lifetime \( \Delta T \) related by \( \Gamma \Delta T \geq \hbar \)).

Low-lying states (bound states) can only decay through \( \gamma \)-ray emissions: their width is of the order of \( 10^{-3} \text{ eV} \).

At much higher excitation energies, known as positive energy states, the width is typically of the order of 0.1–100 keV. These levels may be formed by several typical configurations of nucleons, in particular \( (A + a) \), \( (B + b) \) or \( (C^*_i) \). Each of these configurations is associated with a typical width \( \Gamma_{a}, \Gamma_{b}, \Gamma_{\gamma} \). The sum of all possible configurations \( \Gamma_i \) is related to the total width \( \Gamma \): the higher \( \Gamma \), the shorter the lifetime of the level.

When the incident particle \( a \) is sent on the nucleus \( A \) with a precise energy \( E_{ar} \), the probability of forming an excited nucleus is greater than for any other \( E_a \) energy slightly greater or lower than \( E_{ar} \). For particles of energy \( E_{ar} \), the probability of the emission of a particle \( b \) (and/or a cascade of characteristic \( \gamma \)-rays) is also enhanced.

Owing to competing phase shifts in the quantum mechanical behavior of nuclear reactions, the cross-section may sometimes be very low in the vicinity of a resonant energy. The discontinuities in the cross-section values of nuclear reactions induced by \( a \) on \( A \) give rise to some potential for depth profiling of \( A \) nuclei: signals induced in the detector by \( b \) or \( c \) particles will be particularly intense when arising from those regions in the target material where \( E_a = E_{ar} \). If a material is irradiated with particles \( a \) of energy greater than \( E_{ar} \), the region where \( E_a \) will reach this particular energy \( E_{ar} \) will be achieved at a defined depth below the surface. This depth may be calculated by using the \( S(E_a) \) values of

\[ E_{a0} = E_{a0}m_A \]

\[ E_{b} = \frac{E_{c}m_A}{m_a + m_A} \]

\[ E_{c0} = E_{c0} + Q_c \]

\[ E_{c} = \frac{E_{c}m_A}{m_a + m_A} \]

\[ E_{c0} = E_{c0} + \frac{Q_c}{m_a + m_A} \]

\[ E_{c} = \frac{E_{c}m_A}{m_a + m_A} \]

Figure 3 Mass–energy scheme of a resonant nuclear reaction. The formation in various levels of an excited compound nucleus (CN) (b) by the interaction of an incident particle a on a target nucleus A takes place only for discrete incident \( E_a \) energies (\( E_{c0} \) calculated in the center of mass system). Particles b of various energies \( (b_0, b_1, \ldots) \) are consequently emitted to give rise to a final nucleus B which could appear in various states (c). (From G. Deconninck, LARN. [21])
Table 1 and the corresponding detected $E_b$ values may be calculated by using Equation (7) and the necessary correction for the energy loss in the outgoing direction (see Figure 2) which is to be calculated by using the corresponding $S(E_b)$ values of Table 1.

The depth resolution is directly related to the total width of the resonance: the narrower the resonance, the more precise will be the depth resolution. Useful resonant energies $E_{at}$ for depth profiling are limited for several reasons:

1. The cross-section at the resonant energy must be intense in comparison with its value outside the resonance.
2. The resonant energy must be well isolated in order to avoid superposition of signals originating from various regions below the sample surface where several resonant energies may be reached.
3. The resonance width must be of the order of (or less than) the energy resolution of the whole experimental set-up (taking into account the accelerator energy resolution, detector resolution, detector solid angle accepting particles emitted with various $\theta$ and then various energies ...).
4. The energy straggling of the incident particles into a buried layer under the surface must be sufficiently small, as should be the energy straggling of the emitted particles along its outgoing path and into the necessary absorber (inserted between the target and the detector to stop elastically scattered a particles).

The detection of emitted $\gamma$-rays from the residual nucleus does not suffer from the last uncertainty (straggling in energy of the emitted particle) but $\gamma$-rays may be affected by Doppler shift when the emitting residual nucleus decays before being stopped in the material. Doppler broadening of emitted $\gamma$-rays only arises if the lifetime of the recoiling C* or B* nuclei is shorter than the time required to stop this recoil nucleus in the sample target.

4 IDENTIFICATION OF SIGNALS FOR ANALYTICAL PURPOSES

Modern particle detectors of protons, deuterons, $^3$He and $\alpha$-particles with energies in the megaelectron volt range are now exclusively solid-state detectors: p–n junctions made with crystals of silicon. 

The full energy of the detected particle is converted into pairs of electrons and holes: the number of pairs is strictly proportional to the deposited energy. A reverse polarization of the p–n junction is maintained by an adjustable bias across the desired detector depth, which is at least the range of the particles of maximum energy to be detected. This range may vary from 5 $\mu$m for 1-MeV $\alpha$-particles to 0.6 mm for 7-MeV protons. The energy resolution (width at half maximum of a peak induced by monoenergetic particles) is generally in the order of 8–15 keV for the whole range of these useful energies.

For the highest energies, a succession of detectors mounted as a telescope may be necessary. The associated electronics of these telescopes is tailored in order to collect all the signals induced in the successive detectors coincidentally. For energetic particles, the time delay between the signals produced in two distant thin detectors can be taken into account by measuring the time between the two short signals; in this last case, the time-of-flight of the particle is used. For distant detectors, this time interval is used to identify the mass of the particle only. A third detector, or a set of successive detectors which stop the particle completely, is necessary to determine the energy of the charged particle. The resolution of time-of-flight systems is indeed insufficient to measure the energy of the energetic $b$ particles accurately.

The kinetic energy (converted into a proportional signal in the solid-state detector and possibly the time-of-flight) is a characteristic quantity which allows experimentalists to identify the nucleus which was participating in the nuclear reaction. If this nuclear reaction took place at the surface of the sample and if the emitted particle were directly collected in the backward direction, the energy of this detected particle would be simply given by Equation (7), where $E_a$ is the incident energy delivered by the particle accelerator. In contrast if the reaction took place below the surface, the incident particle reaches this region with a lower energy $E'_a < E_a$. $E'_a$ can be calculated by using the target stopping power along the entrance pathlength $x/cos\alpha_0$ which can also be calculated using the appropriate stopping power of the material for this particle $b$. Dividing the whole distribution of signals from $E_b_{\text{max}}$ to $E_b_{\text{min}}$ into energy intervals with a width of the order of the energy resolution of the experimental set-up (including energy straggling for both incident and emitted particles), it is possible to determine the depth profile of thicknesses ranging from 10 nm to a few microns. The experimentalist must have the ability to certify the origin of signals and to exclude eventual interfering elements (see Figure 4).

Figure 4 shows that particles with identical energies may be emitted with the same incident energy $E_a$ and at the same angle $\theta$ by two different A nuclei. Changing
the energy $E_a$ or the angle of detection are alternatives that may be used to deal with the interferences. It may be helpful to use two detectors at two different angles simultaneously for complicated analyses: interferences between reactions at two different A nuclei do not take place at both angles (see Figure 4a and b). In addition to the measurement of the energy of b particles which identify the target nuclei, the measurement of the intensity of signals with identical energies gives the concentration of these nuclei of interest. The intensity of such signals is governed by the cross-section of the particular nuclear reaction: the greater the cross-section, the better the capability of the nuclear reaction to perform accurate (due to statistics) and sensitive elemental determinations. Knowledge of all characteristics of the nuclear reaction (presence of resonances, angular distributions of emitted particles and elimination of interfering reactions by selecting the best angle of detection) is of prime importance to achieving confident analyses.

All these data may be found in various nuclear data tables\cite{42-45} and handbooks.\cite{46,47}

For $\gamma$-ray detection, large volume (40–100 cm$^3$) Ge(Li) photon detectors of high energy resolution (1.2 keV at 1.5 MeV) are used. They are cooled at liquid nitrogen temperature. Various processes of interaction (photoelectric effect, Compton effect, pair creations) give rise to an extended spectrum from which only the full

\end{figure}
energy peak is selected for γ-ray identification. The efficiency of such a detector is quite high for γ-rays of 2 MeV or less but may also be used at higher energies (Figure 5).

An alternative would be a large NaI or BGO (bismuth germanate oxide) detector (about 1000 cm$^3$) with a very high detection efficiency but with a much lower energy resolution. This kind of detector is particularly useful for depth profiling using $(p,\gamma)$ or $(p,\alpha\gamma)$ resonant reactions involving γ-ray energies of more than 2 MeV. In contrast to particle spectroscopy whose energy is a complicated function depending on $E_a$, $\theta$, $x/\cos \alpha_1$ and $x/\cos \alpha_2$, γ-ray spectroscopy only concerns measurement of the energy of the excited state of the promptly decaying excited B$^*$ nucleus. To profile one element which could give rise to a resonant nuclear reaction (see Table 3) at a particular $E_{ar}$ energy, the $E_a$ energy is progressively increased to allow this resonant reaction to take place at various depths below the surface. For increasing values of $(E_a - E_{ar})$ the resonant reaction would produce γ-rays at depths calculated using the stopping power (Table 1) of the incident particle a only.

Examples of depth profiling using γ-ray or particle spectroscopy will be given in sections 5.1 and 5.6 of this article.

The analytical investigation of large specimens or fragile materials which cannot be introduced in the vacuum sometimes requires the use of external beam geometry. This technique is now widely familiar to PIXE (see PIXE (Particle-induced X-ray Emission)) and PIGE users (see Particle-induced γ-Ray Emission) but may be also tailored for NRA when the outgoing particle has a sufficiently high energy (i.e. for $(d,p)$ reactions) by comparison with the energy of the incident particle. The incident beam crosses a thin foil of metal or of mylar before reaching the sample situated outside the vacuum vessel of the accelerator. The distance in the air between the target and the detector may be finely tuned in order to stop the elastically backscattered a particles completely and allow only b particles to reach this detector. The energy straggling of this incident particle in the exit window and in the air, and the energy straggling of the emitted particle in the sample and also in the air does not allow, in this particular case, depth profiling to be performed.

Figure 5 High-energy part of a γ-ray spectrum obtained with a solid-state Ge(Li) detector during the irradiation of a material containing fluorine. The $\gamma_1$, $\gamma_2$ and $\gamma_3$ peaks are produced by $(p,\alpha\gamma)$ reaction leading to excited $^{16}$O. Both $\gamma_1$ and $\gamma_2$ peaks are broadened by the Doppler effect because of the short lifetime of the corresponding levels of the oxygen nucleus which decays before being at rest in the material. The sharp $\gamma_3$ peaks do not suffer this broadening. Each characteristic γ-ray gives rise to signals in three regions: the full energy peak and two escape peaks corresponding to the loss of one or two of the annihilation photons (511 keV) produced after the initial pair creation. (From G. Deconninck, LARN.\cite{1})
5 EXAMPLES OF APPLICATION

Many laboratories in the world use NRA in the field of materials science. We have selected a few typical results. The first concerns the study of hydrogen distribution in the depth of materials by using a methodology involving the detection of $\gamma$-rays produced by irradiation of energetic $^{15}$N ions to induce a resonant nuclear reaction at various depths in the sample. General problems related to energy straggling, cross-sections and performances of $\gamma$-ray detectors will be discussed.

The second results concern the depth profiling of F and Na in SnO$_2$ coated glass (an insulating material) using simultaneous RBS and NRA techniques at two particular resonant proton energies for $(p,ag)$ reactions. The third application benefits from simultaneous PIXE and NRA for a complete characterization of all the components of a YBaCuO superconductor using a microbeam of low energy deuterons.

We will then present the use of a (d,p) reaction for the study of microregions in the grain boundaries of Au-Si alloys and for the determination of traces of sulfur in ancient gold jewellery artefacts. Nuclear reactions are indeed not sensitive to high $Z$ nuclei owing to the high coulomb barrier, but they offer a unique technique (free of interference) for studying light elements in heavy matrices. The last application concerns the determination of all the major and minor elements and a majority of trace elements (in the region of a few micrograms per gram) in a reference material of biological interest.

5.1 Analysis of Hydrogen in Various Materials

The use of megelectron volt ion beams to analyze materials for hydrogen has been more interesting and more important than even the early researchers in this field realized. The reasons for this are simple:

1. Hydrogen is probably the most common contaminant element, especially in thin film materials.
2. Hydrogen has important effects on the chemical, physical and electrical properties of many materials.
3. The analysis for hydrogen is difficult or impossible by most traditional analytical methods.

Megaelectron volt ion beams to probe for hydrogen may be used in two different approaches. The first is NRA, in which megelectron volt ions bombard a sample, inducing nuclear reactions between the incident ion and hydrogen in the target. The second is ERD in which megelectron volt ions bombard a sample and through elastic collisions cause hydrogen ions to recoil out of the sample with the number of these recoils used to determine the amount of hydrogen in the target. This last problem (of ERD) is treated in Elastic Recoil Detection Analysis. The basic principle for hydrogen analysis using NRA is to use nuclear reactions between protons and light nuclei but in the reverse direction: light nuclei are incident particles and hydrogen is the collided nucleus.

While many nuclear reactions are possible for hydrogen analysis, the reactions most commonly used to probe for $^1$H in material are those induced by $^{15}$N and $^{19}$F. These reactions are similar in many ways: they both have low-energy isolated resonances above a few megelectron volts. Another reaction which is capable of profiling much deeper into samples uses a $^7$Li beam. The important parameters for most useful reactions for H analysis are given in Table 4.

The use of the $^{15}$N reaction as a probe for hydrogen is given here as an illustration of this approach. The nuclear reaction is:

$$H(^{15}N, ag)^{12}C$$

The very narrow and intense resonance is shown in Figure 6. The $\gamma$-ray intensity at the resonant energy is four orders of magnitude higher than the one off-resonance.

A beam of $^{15}$N ions is incident on the sample being analyzed and the yield of characteristic $\gamma$-rays of $^{12}$C is measured. Because this is a resonant reaction, the cross-section is large at the resonance energy ($E_{res}$) and small off-resonance. Therefore, if a sample is bombarded with $^{15}$N ions at the resonance energy, the yield of $\gamma$-rays is proportional to the hydrogen only present at the surface.

Figure 6 Variation of the cross-section of the reaction H(\(^{15}\text{N}, ag\))\(^{12}\text{C}\) for increasing \(^{15}\text{N}\) incident ions. The cross-section increases by at least four orders of magnitude at the resonance energy (\(E_i\): 385 MeV). (Data are taken from Horn and Lanford\(^{51}\)).

of the sample. If the beam energy is raised above the resonant energy, there is no longer a reaction with surface hydrogen (because the \(^{15}\text{N}\) ions are above the resonant energy) but as the ions lose energy when penetrating the sample, they reach the resonant energy at a particular depth: the yield of \(\gamma\)-rays is then proportional to the hydrogen content at this depth.

Characteristic \(\gamma\)-rays from the reaction are detected by a large (and therefore efficient) scintillation detector (NaI), or a BGO detector, located close behind the irradiated samples.

The \(\gamma\)-ray yield is proportional to the energy integrated area under the Breit–Wigner formulae for a resonant cross-section, i.e. proportional to \(\sigma_0\Gamma\), where \(\sigma_0\) is the cross-section at the resonance energy and \(\Gamma\) is the width of the resonance. The yield of \(\gamma\)-rays is also inversely proportional to the energy loss of the incident ions. This is because the yield of \(\gamma\)-rays is proportional to the amount of H per cubic centimeter within the resonance detection window (i.e. when the energy is on-resonance) and this is proportional to the thickness of the resonance detection window. This thickness is inversely proportional to \(dE/dx\).

As in all resonant nuclear reaction profiling, a measurement of the number of \(\gamma\)-ray signals induced by the nuclear reactions versus incident energy is made. A known standard material containing a known quantity of hydrogen at a well-defined depth is used for quantitative determination of depth profiles in the material to be studied.

The matrix of this reference material may be different from the matrix of the material under investigation. All the matrix effects are contained in \(dE/dx\) which is matrix-dependent.

The depth resolution (\(\Delta x\)) of the method depends on the measured full width at half maximum (fwhm) of the hydrogen profile, for an infinitely thin layer of hydrogen at a certain depth in the sample. This is then determined by the width of the reaction resonance (\(\Gamma\)) and the fluctuations in the energy (\(\Delta E\)) of the bombarding ions at this depth in the sample. \(\Delta E\) has contributions from the energy spread in the incident proton beam (\(\Delta E_b\)), which depends on the performance of the accelerator, energy straggling (\(\Delta E_s\)) (see Equation 2) and, for detection of \(\gamma\)-rays, the Doppler energy broadening (\(\Delta E_D\)). Since in most cases these are all Gaussian distributions, the total energy width is obtained by adding them in quadrature, Equation (9):

\[
\Delta E^2 = \Delta E_b^2 + \Delta E_s^2 + \Delta E_D^2
\] (9)

For the depth profile at the extreme surface, the energy straggling is not Gaussian and another more sophisticated procedure is involved.\(^{52}\) Some additional explanation is given for Doppler effect. Hydrogen atoms in materials are not stationary but vibrate. For a narrow nuclear resonance, this motion can shift the reaction on- and off-resonance. For example, the width of the \(^{15}\text{N}\) resonance is 1.8 keV, whereas the Doppler broadening is in the range 5–15 keV, depending on the strength of the hydrogen bond. This contribution is nevertheless usually small compared to straggling, except when analyzing very thin hydrogen surface layers where the Doppler effect is the dominant source of broadening.
The ideal nuclear reaction for profiling would be one with an infinitely narrow resonance reaction with a zero cross-section off-resonance. The $^{15}$N nuclear reaction is nearly this ideal. The off-resonance cross-section is more than four orders of magnitude smaller than the peak resonance cross-section. For other resonance reactions, the off-resonance cross-sections are generally much larger.

However, even in this favorable case, there are situations where the nonzero off-resonance cross-section needs to be taken into account. Thus, a layer of TiH$_2$ on clean Si was profiled.$^{(51)}$ The results of this profile are shown in Figure 7. The counts above 7.2 MeV essentially all come from the off-resonance cross-section.

The correction for such off-resonance effects is simple. Since the off-resonance yield is proportional to the on-resonance energy $\gamma$-ray yield (integrated between 6.4 and 7.2 MeV in Figure 6) times the off-resonance cross-section, once the proportionality constant is known, these off-resonance counts are subtracted from the total counts. In the case of $^{15}$N NRA, this correction is

$$Y_{\text{off res}} = (1.28 \times 10^{-5}) I$$

where $I$ is the energy integrated on-resonance yield (in counts $\text{keV})^{(51)}$.

This correction is simply due to the fact that no other resonance at higher energy (the next one being at $E_{\text{inc}} = 18 \text{MeV}$) in the $^{15}$N + $p$ reaction gives a contribution.

The problem of sensitivity or limit of detection is discussed now. When making NRA measurements where the reaction product is a high-energy $\gamma$-ray, the detectors are also sensitive to background radiations, such as cosmic rays and, in some cases, accelerator-generated radiation. This background is the main factor in the limitation of the sensitivity of NRA. There are several ways in which sensitivity can be improved, the first being by high beam current. Since the external background is independent of the beam current whereas the real count rate increases linearly with this beam current, sensitivity improves linearly with beam current. However, this approach can be used only up to the limit of the beam current available in a particular accelerator or the limit of beam current
that a particular sample will withstand. The last limitation may be avoided by rastering the beam along a large area on the surface for samples where the surface homogeneity is guaranteed.

Another approach is to build material and electronic shields to reduce the background in the $\gamma$-ray detectors. This approach is now much easier with the advent of bismuth germinate BGO scintillation detectors which are progressively replacing the usual NaI scintillator. BGO detectors are much more efficient (for a given size) than NaI and are much less sensitive to neutrons generated by cosmic rays.

In good cases, sensitivities of the order of micrograms per gram and depth resolutions of a few nanometers are possible. However, the practical limit achievable is dependent on the nature of the sample being analyzed and on the quality of the accelerator (energy resolution, beam current intensity, etc.) and its associated equipment.

Historically, NRA has been used in many studies of hydrogen in materials. However, because of the wide availability of new facilities for He ERD and because of the potential of high-energy heavy ion ERD, this alternative method is becoming more popular (see Elastic Recoil Detection Analysis).

Nuclear reactions may also be used for the study of the other isotopes of hydrogen. Some of the reactions that have been used include: $^2\text{H}(d,p)^3\text{He}$, $^3\text{H}(d,n)^4\text{He}$, $^3\text{He}(d,p)^4\text{He}$, $^3\text{H}(d,n)^4\text{He}$ and $^3\text{H}(p,n)^3\text{He}$. For all reactions giving rise to neutrons, the analytical technique involves the detection of the associated charged particle.

The most widely used reaction for deuterium analysis is the $\text{D}(^3\text{He},p)^4\text{He}$ reaction\(^{53}\) which has a positive $Q$-value (18.35 MeV) making identification of the reaction products easy and the elimination of interfering signals comfortable using a coincidence technique with the detection of both particles simultaneously emitted: $p$ and $^4\text{He}$. Depth information is obtained by the energy loss of the outgoing $^4\text{He}$ particles. The cross-section for this reaction is not large (70 mb at 0.75 MeV) compared to the elastic cross-section (see Elastic Recoil Detection Analysis), so count rate problems are of concern.

### 5.2 Depth Profiles of F, Na in SnO$_2$ Coated Glass

A typical application of simultaneous RBS and resonant NRA is the study of fluorine and sodium migration in a SnO$_2$ layer deposited on a glass substrate\(^{54}\). The depth profiles are measured by proton-induced resonant reactions. The depth calibration which is essential to localize the interface is done by proton backscattering on Sn. As the SnO$_2$ layer is thin (200 nm), the same stopping power may be used for incoming protons and outgoing elastically scattered scattered protons on Sn, the heaviest element in the sample. The fwhm of the Sn signals is therefore twice the actual energy loss ($\Delta E_p$) of the incoming protons in the SnO$_2$ layer. $\Delta E_p$ then gives the exact position of the interface of SnO$_2$ with the bulk glass in terms of energy, without using the stopping power parameters. RBS is therefore used to calibrate the resonant reaction excitation curves.

Profiling of sodium is carried out by using the $^{23}\text{Na}(p,\gamma)^{24}\text{Ne}$ at the resonance energy $E_R = 1010.5$ keV (resonance width $\Gamma_R < 0.5$ keV). $\gamma$-rays of 1634 keV are detected in a 4 in $\times$ 4 in NaI detector offering maximum efficiency. The target sample is irradiated into the well of the NaI detector. As it is essential to reduce the irradiation duration to prevent sodium migration induced by the beam, the beam is rastered on the sample in order to avoid local overheating of the glass. The experimental excitation curve is displayed in Figure 8(b). A small surface concentration is observed followed by a steep edge at $E_p = E_R + 14.6$ keV, and then a constant concentration of 16 atom% (the bulk concentration of Na in glass). The RBS spectrum was collected simultaneously. Figure 8(a) shows this RBS spectrum for the SnO$_2$ layer on glass under the same experimental conditions as used for the profiling, i.e. $E_p = 1.015$ MeV. The width $2\Delta E_p$ of the Sn signal as measured on the RBS spectrum is 29.2 keV (twice 14.6 keV) and can be related directly to the step in the Na depth profile. The exact localization of the concentration step with respect to the interface is therefore known directly, without any calculation using physical parameters such as the stopping power of the Sn and O mixture. Therefore, any other element that could be present in the layer and whose measurement is not accessible by either RBS or NRA methods will not disturb the measurement.

Profiling of fluorine is done using the $^{19}\text{F}(p,\gamma)^{20}\text{O}$ at resonance energy $E_γ = 340$ keV ($\Gamma_R = 2.4$ keV). The $\gamma$-rays in the range of 6–8 MeV are also detected using the large NaI scintillator. The excitation curve is displayed in Figure 8(d) showing a shallow concentration followed by a huge peak localized in the SnO$_2$ layer, close to the interface with the glass substrate, and just in front of the sodium step. The energy loss $\Delta E_p$ corresponding to the interface was, once again, measured by the backscattering spectrum which was collected simultaneously in the same way as in Figure 8(c). Once more, the width of the Sn peak is twice the energy loss of the protons measured by the new RBS spectrum. Using these two resonant nuclear reactions, it was then possible to localize the relative position of (i) the fluoride layer (completely in the SnO$_2$ surface layer), (ii) the interface between SnO$_2$ and the glass, and (iii) the sodium step which is located entirely in the glass substrate.
Figure 8 Determination of Na profile by the $^{23}$Na(p,γ)$^{20}$Ne reaction around the resonant energy (1010.5 keV). The Sn thickness was determined at 1 MeV by RBS (a) and the step in the γ-ray production indicated that Na is only present in the glass substrate behind the SnO$_2$ coating (b). Similarly, the F profile is determined by the $^{19}$F(p,γ)$^{16}$O reaction around the resonant energy at 340 keV. The corresponding RBS spectrum at 340 keV (c) gives the same SnO$_2$ thickness as in (a) and the F profile (d) indicates that this element is mainly present in the SnO$_2$ coating. (Reprinted from G. Terwagne, G. Deconninck, ‘Concentration Profile of Light Elements Near an Interface’, Nucl. Instrum. Methods Phys. Res., Sect. B, 64, 153–155, Copyright (1992), with permission from Elsevier Science.)

5.3 Stoichiometry of Y–Ba–Cu–O Superconductors

In addition to crystallographic characterization and measurement of thermal and electrical properties of superconducting materials, rapid and nondestructive analytical techniques involving milliprobe facilities were developed to search for the best conditions for their synthesis and to test the stoichiometric composition of YBa$_2$Cu$_3$O$_{6.5+x}$.

Irradiation of pellets made from a powder superconductor with 2 MeV deuterons may give, at the same time, the relative bulk concentration of all the elements. A beam of deuterons is focused on a narrow region (5 µm) of the pellet. A solid-state particle detector, situated at 135° relative to the incident beam, collects protons from (d,p) reactions on O and C. A low carbon content is always possible from the precursors used in the synthesis (BaCO$_3$) or from a deposit on the sample surface by the incident deuteron beam of some residual atoms from oil used in the pumping set-up. The elastically scattered deuterons are stopped in a mylar foil of appropriate thickness inserted between the irradiated surface and the detector. Simultaneously, a Si(Li) detector collects X-rays, L X-rays of Ba and K X-rays of Cu and Y which are used as analytical signals for the rest of the elements. A second solid-state detector is installed at 170° relative to the incident beam and is used to collect the elastically backscattered deuterons in order to check the homogeneity of the Y, Ba and Cu distribution at depth. A flat plateau of Ba, Y and Cu in the RBS spectrum would certify this homogeneity. The deuteron beam is rastered on the surface. The integrated time of the whole measurement is of the order of 1 h to create a map of the four elements in an area of $40 \times 40$ spots of 5 µm wide.
A typical proton spectrum is shown in Figure 9(a). Carbon signals from surface contamination appear in region D. Carbon signals from the bulk material (region C) are to be subtracted from regions of oxygen signals (regions A and B). The subtraction of the carbon contribution in regions A and B of oxygen in the bulk (A) and at the surface (B) is performed by calculating the relative contribution of carbon in (C) and in the corresponding regions A and B of the proton spectrum collected on a pure carbon homogeneous standard sample (Figure 9b).

Using the pure RBS cross-section on Cu, Y and Ba, the stoichiometric determination of heavy compounds (expected to be $Y_1Ba_2Cu_3$) was $Y_1:Ba_2Cu_3:O$ (Ba$_2$ as reference).

The accuracy of the measurement of O concentration ($7 \pm 1$) by RBS was not sufficient because of superposition of the O signals on to the huge contribution of the heavier elements. The accuracy of the O content using results of the (d,p) reaction, is of the order of 3% (statistical accuracy).

Materials showing the strongest Meissner effect (levitation of a small magnet) at liquid nitrogen temperature are also those showing the best homogeneity in Cu, Ba and Y concentrations in $5 \times 5 \times 5\mu m$ regions analyzed (Figure 10a and b). Possible local nonhomogeneities in several samples show that Ba and Y are related. The ternary diagrams of three of the four components (Y, Ba, Cu, O) indicate that, as far as the most homogeneous material is concerned, local discrepancies from the ideal $Y_1Ba_2Cu_3$ composition are mainly observed in the Y content, the reason lies only in the poor statistical accuracy on K X-rays of Y induced by 2 MeV deuterons. An improvement in the accuracy of Y determination is achieved when the same sample is studied by PIXE induced by 3 MeV protons. The distribution of the points in a ternary diagram involving O, Cu and Ba as extracted from numerical results on the homogeneous material (Figure 11a) is not of statistical origin, but indicates some nonhomogeneity in the microscopic distribution of oxygen. For the second (nonhomogeneous) sample, the nonhomogeneity is so great that the points are scattered far from the ideal position: the center of the triangle. Nonhomogeneities in the O concentration of Figure 11(b) cannot be correlated with the presence of any specific oxide (CuO, Y$_2$O$_3$, BaO, etc.). For the homogeneous sample, the local concentration of oxygen exhibits variations of about 10% around the expected value of 6.7. The reason could be the presence, in the synthesized sample, of copper in two different valence states ($2^+$ and $3^+$).

The experimental accuracy on the relative concentrations of Cu, Ba and O, using simultaneously PIXE and (d,p) reactions, was less than 3%.

### 5.4 Three-dimensional Microanalysis of a Gold–Silicon Eutectic Alloy

A film of silicon was deposited on pure polycrystalline gold foils, previously rolled down to thicknesses ranging from 10 to 20 $\mu m$. The deposition was performed with an electron gun at low pressure. The amount of evaporated silicon was adjusted in order to obtain films up to 1 $\mu m$ thick on the gold substrate. This substrate was maintained at 400°C during the silicon deposition, a temperature which is slightly higher than the eutectic temperature (363°C). At this temperature a liquid Au–Si mixture diffuses, during the deposition procedure, in the gold foils (Figure 12) but only along well-defined paths, the gold grain boundaries. K X-rays of Si induced by PIXE (Particle-induced X-ray Emission) clearly indicate that a gold–silicon alloy has diffused on the surface of the foil by forming characteristic leaf-shaped decorations starting from the boundaries of the gold grains which were flattened by the rolling procedure. Several of these decorations are shown in Figure 12a. The formation of silicon leaves on the surface of the foil is clearly visible in Figure 12b. The experimental accuracy on the relative concentrations of Cu, Ba and O, using simultaneously PIXE and (d,p) reactions, was less than 3%.
Figure 10  Concentration maps of Ba, Cu, Y and O in bulk superconductors. Concentrations are presented by 64 gradations of gray. The maximum values are, respectively, in each pixel: 8192 for Ba(L), 4096 for Cu(Kα), 256 for Y(Kα) and 1024 for O (protons). The beam diameter is less than 5 µm and the distance between steps is 10 µm. (a) Homogeneous YBaCuO sample; (b) Nonhomogeneous YBaCuO sample. (Reprinted from G. Demortier et al., ‘Stoichiometric Characterization of Y–Ba–Cu–O Superconductors With Nuclear Probes’, *Nucl. Instrum. Methods Phys. Res., Sect. B*, **30**, 491–496. Copyright (1988), with permission from Elsevier Science.)

Figure 11  Ternary diagram of Cu, Ba and O for a homogeneous sample (a) and a nonhomogeneous one (b). (Reprinted from G. Demortier et al., ‘Stoichiometric Characterization of Y–Ba–Cu–O Superconductors With Nuclear Probes’, *Nucl. Instrum. Methods Phys. Res., Sect. B*, **30**, 491–496. Copyright (1988), with permission from Elsevier Science.)
flattened grains may occupy the whole thickness of the foil. Therefore, the diffusion of the liquid phase took place through the whole gold foil thickness. The diffusion is so fast (a few minutes at such a low temperature cannot be explained by a process of solid state diffusion) that nothing other than a liquid phase of gold–silicon eutectic alloy could diffuse. The atomic concentration of Si in this eutectic alloy is 19% (about 3.2% Si by weight).

The depth profile of Si in gold is taken using a (d,p) reaction. The nuclear reaction $^{28}\text{Si}(d,p)^{29}\text{Si}$ ($Q = 6.25\text{ keV}$) (leaving the residual $^{29}\text{Si}$ nuclei in their fundamental energy level) is mainly governed by neutron capture involving no exchange of angular momentum ($\ell = 0$). As a consequence, the maximum intensity of the proton emission is achieved in the forward direction. The cross-section at $\theta = 0^\circ$ of this nuclear reaction at $E_d = 2.8\text{ MeV}$ is quite large at 6 mb sr$^{-1}$. We then chose to detect the emitted protons in the forward direction. In this special arrangement, the proton detector is situated into the incident deuteron beam (Figure 13). As incident deuterons of 2.8 MeV cannot cross the coulomb barrier of a Au nucleus, the (d,p) nuclear reaction can only take place with light nuclei. Therefore, the detected proton spectra contain only information on Si. A 20 $\mu$m thick absorber of pure gold is inserted between the sample to be studied and the detector in order to stop the incident deuteron beam completely even when the beam would cross a hole in the gold–silicon sample. The choice of a material containing only a heavy element (Au) as the absorber prevents any production of additional protons in this gold absorber during the deuteron irradiation.

The quantitative determination of silicon at different depths below the surface is based on the comparison of proton spectra obtained when ultrapure silicon and gold–silicon samples in the same geometrical

---

arrangement are bombarded. The silicon reference material is a thin foil (75 µm thick) of Si used in semiconductor technology. The corresponding depths in pure silicon and in gold–silicon alloys are calculated using the relative stopping power of pure silicon and that of the eutectic gold–silicon alloy (Figure 14). To scan the sample, a proton microbeam (5 µm × 5 µm) is rastered on the surface along 50 µm × 50 µm regions, a surface involving more than the area of one single flattened grain.

If the deuteron beam hits a gold grain boundary in which the diffusion of the eutectic alloy took place, a proton spectrum like that of Figure 14(a) may be observed showing a more important contribution in the medium and the low energy parts of the p₀ broad “peak” than when this deuteron beam hits a uniform silicon sample (Figure 14b). The depth distribution of Si in this particular case indicates that the relative concentration of Si is increasing from the surface to a region buried at several microns below the surface.

The map of Figure 15 corresponds to the silicon distribution at various depths below the surface irradiated at the rear part of the prepared gold foil. Figure 15(a) reflects the Si concentration at the bottom of the prepared foil which is reached by the most energetic protons. The regions of the proton spectrum shown in Figure 14(a) show schematically the corresponding regions in the depth of the 12-µm thick irradiated specimens. The incident beam was directed onto the face of the gold foil opposite to the face on which the Si deposition was made. In any region the silicon concentration does not exceed a few percent, a concentration well below that of the eutectic composition. This eutectic concentration is observed in Figure 15(i) which corresponds to grain boundary regions at the point where deuterons exit and at the surface where the silicon was deposited.

Nevertheless, in regions where silicon is detected only a liquid phase with a composition close to that of the eutectic could be admitted. The diffusion takes place so rapidly (a few minutes) that no appreciable solid state diffusion could be expected. Each concentration of silicon lower than 19% (as observed in nearly all parts of each map) can be understood by considering that the size of a grain boundary is narrower than the area of the incident deuteron beam. Scans like those of Figure 15 may then be converted into measurements of the width of the grain boundary filled with the eutectic alloy, the ratio of the measured silicon concentration on the eutectic composition being the ratio of the width of the grain boundary to the beam diameter.

5.5 Determination of Traces of Sulfur in Ancient Gold Artefacts

Investigations of the composition of archaeological artefacts made from precious metals require the use of nondestructive analytical techniques. PIXE and PIGE have been successfully applied in our laboratory for topographical elemental analysis of Fe, Cu, Zn, Ag, Cd, Sn and Au in uncorroded surfaces of jewellery items. The composition of the material in narrow regions of tiny solders on antique gold artefacts may give valuable information about the workmanship of ancient goldsmiths. In various papers, the hypothesis that in ancient times cadmium sulfide (a yellow mineral with a color close to that of gold) may have been “alloyed” with gold to obtain a material suitable for brazing has
Figure 15 Set of nine maps corresponding to the nine slices of Figure 14. Symbols (a) to (i) refer to the nine layers in the 12 μm thick sample. (Reprinted from S. Mathot, G. Demortier, ‘Three-dimensional Nuclear Microanalysis in Materials Science’, Nucl. Instrum. Methods Phys. Res., Sect. B, 77, 312–319. Copyright (1993) with permission from Elsevier Science.)

been discussed. To test this hypothesis an experimental procedure for analyzing traces of sulfur in gold artefacts was developed. It is indeed expected that during the antique alloying procedure, traces of sulfur from cadmium sulfide were introduced in the brazing alloy.

Detection of energetic protons induced by deuteron bombardment of the specimen under investigation was achieved. The detector was situated at an angle of 135° with respect to the incident deuteron beam in order to facilitate the study of thick specimens often with an irregular shape. Sheets of mylar of uniform thickness (2.9 mg cm⁻² each) were inserted between the target and the detector in order to stop the scattered deuterons completely. Owing to the fact that most of the (d,p) reactions have a large positive Q value, the proton energies are not significantly reduced by these absorbers.
The best experimental condition for sulfur determination is obtained at $E_d = 1.9\,\text{MeV}$, in which case the cross-section is sufficient and the $p_0$ and $p_1$ peaks are well resolved.$^{(57)}$ Since the cross-section for $1.7\,\text{MeV}$ deuterons is greater than at $1.9\,\text{MeV}$, working conditions at $1.9\,\text{MeV}$ (on a thick sample) allow us to check for the presence of sulfur in the bulk and not only at the surface. Possible interfering elements (with their appropriate $Q$ values) are within the scope of (d,p) reactions on S: Si, Mg, Cl, Ca (for $p_0$) and Al, P, Cl, K, Mg (for $p_1$).

The choice of detection angle and incident deuteron energy was then a determining factor in eliminating the

---

**Figure 16** Experimental results from a (d,p) reaction induced on gold alloys prepared by an antique procedure (a) and in a soldering region of an antique jewellery artefact of the 9th century A.D. (b) Several peaks indicate the presence of Si and S. (Reprinted from G. Demortier, A. Gilson, 'Determination of Traces of Light Elements in Gold Artifacts Using Nuclear Reactions', *Nucl. Instrum. Methods Phys. Res., Sect. B*, 18, 286–290. Copyright (1987) with permission from Elsevier Science.$^{(57)}$)
possible interferences. Detection of \( p_0 \) and \( p_1 \) protons provided a check for an interference-free investigation. This is because of the presence of both \( p_0 \) and \( p_1 \) signals for S outside the regions for Al(\( p_0 + p_1 \)) and (Si \( p_0 \)) and the relative intensities of these peaks in comparison with a reference sample.

Sulfur and silicon (which were always introduced in metals when heating ores in antique metallurgy) are of crucial importance in understanding ancient technologies. Sulfur (in blende and greenockite) and silicon (in many minerals) may be expected to be present in narrow parts of the solder formed during the antique brazing of gold. Figure 16(a) shows the analysis of a soldering alloy that we prepared using this antique procedure: gold–cadmium alloys (with low melting point) are obtained by direct dissolution of CdS in a previously melted drop of gold. The concentrations of S and Si detected are, respectively, 120 ppm and 50 ppm. Note also the presence of C (from \( ^{13}\text{C} \)) as an extra signal arising from the experimental set-up, i.e. a carbon (from oil in the pumping system) deposit on the target during the deuteron irradiation. The mylar absorber must have a thickness of 25 mg cm\(^{-2}\) in order to eliminate also protons from

\( ^{a} \) This low oxygen concentration, determined by neutron activation analysis, is not reliable with the expected value for a biological sample.
NUCLEAR REACTION ANALYSIS

(d,p) reactions on $^{12}$C. The concentration of Cd could be determined simultaneously by detection of characteristic X-rays induced by the same deuteron beam. The presence of residual sulfur (only at trace level) indicates that at least 95% of S was lost during the alloying procedure.

Figure 16(b) was obtained during the irradiation of a region of a soldered gold granule on a hollow gold pearl found in Syria (Hauran) with other more prestigious objects of Byzantine jewellery (9th century A.D.) (Figure 17).

The information from S (at concentration 30 ± 7 ppm) cannot be easily isolated from the large contribution of Si at the surface. The width of the peaks of Si present in this ancient artefact is much narrower than those observed in pure Si and in the soldering alloys formed by the methods available in antiquity (Figure 16a). The presence of traces of Si and often also traces of Al, can be attributed to dust inclusions in narrow regions of “porous” solders.

5.6 Particle-induced X-ray Emission, Particle-induced γ-ray Emission and Nuclear Reaction Analysis for Elemental Analysis of a Biological Reference Material

Bowen’s kale,($^{58}$) a powder obtained by dry freezing this vegetable, was widely distributed in various laboratories to be certified for a reference material. Using various IBA techniques, it was possible to determine most of the main elements and traces quantitatively. Table 5 summarizes these results.($^{59}$)

NRA induced by protons and deuterons was used for the determination of B, C, N, F and Na. The choice of a specific incident energy and the selected identification signal were determined for interference-free determination.

Compositions of various elements (from P or Ca) were obtained at low energy PIXE in order to minimize the X-ray absorption into the target itself. Traces of higher Z elements were found using PIXE at 1.7 MeV in order to improve the sensitivity. Determination of hydrogen was not possible due to the rapid destruction of the sample powder during heavy ion irradiation (for ERD or NRA using $^{15}$N). The concentration of oxygen was established at 43%, a more reliable value than the previous determination using neutron activation analysis. The total content of this reference material using PIXE, PIGE and NRA exclusively (hydrogen not included) is 98.9 ± 3.5%.

NUCLEAR REACTION ANALYSIS

Breath analysis is the sampling and analysis of an analyte in the exhaled breath of living animals, and the subsequent interpretation of the results. Breath sampling is noninvasive of the body as is urine sampling, unlike blood sampling. All three modes of biological monitoring can be very useful and often are necessary. Breath sampling is especially useful for chemically inert volatile organic compounds (VOCs).

The related branches of scientific endeavor include:

- **Pulmonary function testing** is the measurement of pulmonary parameters to diagnose pulmonary disorders.\(^{(2)}\)
- **Pulmonary toxicology** is the study of adverse effects of inspired toxicants on the respiratory system.
- **Inhalation toxicology** is the study of adverse effects of inspired toxicants on body target organs and tissues. Pulmonary toxicology is thus a subset of inhalation toxicology. The health consequences of “sniffing” chemicals and “poppers” are included. Many scientists use inhalation toxicology as a term to describe animal experimentation.
- **Anesthesiology** is the intentional exposure of anesthetics in nonadverse doses to humans to aid medical operations where pain would be excessive.
- **Taste and odor science** is the investigation of taste and odor in inspired breath and oral ingestion from natural sources (decaying vegetation, decomposing bodies, and environmental odors) and synthetic sources (food, drink, drugs, cosmetics, perfumes, toiletries, wine tasting and bouquet, beer taste and odor, sewer headspaces and emissions, pesticide applications, garbage and waste sites, natural and potable waters), and environmental and indoor air quality situations. Often taste and odor panels are a part of the evaluation of such phenomena. When used for risk assessment purposes, taste, odor, and other aesthetic considerations are called organoleptic criteria.

This article will focus on human exhaled breath analysis, except where specified otherwise.

1 HISTORY

Breath analysis has been used for many years:\(^{(1–9)}\)

- As a diagnostic technique of good health, as part of medical monitoring. The Hippocratic physicians (Hippocrates of Cos 469–399 BC) and Aristotle (384–322 BC) recommended that physicians sniff the breath of their patients as part of health assessment. Halitosis is defined as bad breath. Modern pulmonary function testing dates from 1846 from the invention of the water spirometer to predict people who would later develop tuberculosis.\(^{(2)}\) The maximum voluntary ventilation test was described in 1933. Reference ventilation values for Caucasians were

---

*Encyclopedia of Analytical Chemistry*
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd
first designated in 1948, but it was not until the late 1950s that the technique was applied to detect occupational lung diseases after the invention of waterless spirometers.

- To assess blood alcohol content, for example for drink-driving testing and in forensics. The alcohol breath test was developed in the 1950s.
- To determine if exposure has occurred to xenobiotics as part of biological monitoring in the workplace. The biological exposure indices (BEIs) of the American Conference of Governmental Industrial Hygienists (ACGIH) were first formulated in 1983.\(^{(1)}\)
- To determine if exposure has occurred to xenobiotics as part of biological monitoring in indoor air. The Total Exposure Assessment Methodology (TEAM) studies of EPA have involved breath testing in at least 800 residents since 1979.\(^{(1)}\)

2 THE RESPIRATORY SYSTEM

The purpose of the respiratory system (respiration means to breathe again) is to provide inhaled oxygen \(O_2\) in air to oxygenate the blood, and to allow exhalation of waste gases such as the ultimate gaseous products of metabolic oxidation (carbon dioxide \(CO_2\), carbon monoxide \(CO\), sulfur dioxide \(SO_2\), and nitrogen oxides \(NO_x\)), and the ultimate gaseous products of anaerobic metabolism (hydrogen \(H_2\), methane \(CH_4\), hydrogen sulfide \(H_2S\), and ammonia \(NH_3\)). Xenobiotics are breathed in and out adventitiously.\(^{(1)}\)

The respiratory system consists of two lungs and the tubes through which air reaches them and is also expelled. An inspired breath through the nose flows through the nasal cavities to the pharynx, to the larynx or voice box, and then into the trachea or windpipe. Air then continues into the bronchi, one going to each lung. The bronchi subdivide into bronchioles and keep subdividing until the smallest microscopic air sacs are reached, the alveoli.

The alveoli are the sites of \(O_2\) and \(CO_2\) exchange with the blood across a thin double membrane, the intermembrane fluid being piped into the lymph system. Mouth breathing directs outside air into the pharynx.

The easiest access to the blood by xenobiotics is when they are in the form of gases (1 mole of the compound at ambient conditions is completely in the form of a gas) or vapors (the gaseous phase of a compound that is a liquid or solid at ambient conditions). Aerosols are deposited in the respiratory system according to particle size. All aerosol sizes that can be conducted through the nasal passages are termed “inhalable” and are \(<100\mu m\) in aerodynamic diameter (the diameter of the equivalent sphere of density \(1\, \text{g}\, \text{cm}^{-3}\) of the same terminal velocity as the test particle). Those that penetrate into the alveoli (\(<10\mu m\) in aerodynamic diameter) are termed “respirable”. The fraction that is inhalable but not respirable is termed “thoracic”. Particles \(\leq 0.1\mu m\) and between 0.5 and 5.0\(\mu m\) in aerodynamic diameter deposit efficiently in the alveoli. Those between 0.1 and 0.5\(\mu m\) in aerodynamic diameter are not efficiently deposited and may also be breathed out.\(^{(1)}\)

The compartments of the nose, pharynx, larynx, trachea, and bronchi contain mucus cells. They contain cells that are ciliated to sweep deposited foreign particles towards the esophagus to be swallowed with the saliva. Thus large particles are ingested rather than being absorbed through the lungs or exhaled.

2.1 The Nose

The function of the nose is to humidify and filter the air, and bring it to body temperature. The nose contains the receptors for odor. The two nostrils contain hairs which prevent large particles from entering beyond, to the two nasal cavities that are separated by the nasal septum. Large aerosols \(>10\mu m\) in aerodynamic diameter deposit in the nose. Three bony projections, the conchae, project from the back walls of the nose. All the surface cells in the nasal cavities are ciliated, and beat towards the throat. The sinuses in the bones of the skull near the nose are connected to the nasal cavities.

2.2 The Mouth and the Throat

The nasal cavities connect directly to the pharynx (throat) via the nasopharynx, then to the oropharynx directly behind the mouth, and then to the laryngopharynx that leads to the larynx. Just down from the opening to the larynx (the glottis) is the smaller opening into the esophagus, part of the digestive tract. Large particles deposit on the tongue and on the walls of the mouth and pharynx in mouth breathing.

The larynx or voice box is supported by rings of cartilage in its walls. It contains the vocal cords which vibrate during exhalation. During swallowing, the larynx is sealed off by the epiglottis. When particles enter the larynx, coughing is the reflex.

2.3 The Windpipe

The trachea or windpipe extends from the larynx to the middle of the chest and is also supported by C-shaped rings of cartilage. Irritation causes sneezing.

2.4 The Bronchi

The trachea divides into the right and left bronchus, each leading to a lung. The bronchus enters each lung...
at a depression called the hilus, where blood vessels and nerves also enter each lung. The progressive subdivision of primary bronchi, to secondary bronchi, to bronchioles, to the alveoli is referred to as the bronchial tree. The bronchi and bronchioles are supported by C-shaped rings of cartilage like the trachea.

2.5 The Lungs

Each lung has more than a million bronchioles. Each bronchiole leads to a cluster of alveoli. The wall of each alveolus consists of a single layer of epithelial cells and elastic fibers that allow stretching and contraction. Each alveolus is surrounded by a network of capillaries, the deoxygenated part being from the pulmonary artery, and the oxygenated part emptying into the pulmonary vein. The distance across the alveolar membrane and the capillary membrane is about 500 nm. Alveoli are coated with lung surfactant (mostly C16 fatty acid lecithins) to prevent them from collapsing. The major mechanism for removal of microorganisms and particles in the alveoli is engulfment by pulmonary alveolar macrophages. The effective surface area of the alveoli is about 70 m².

The lungs occupy the thoracic cavity, the right lung having three lobes and the left, two. The lungs are separated physically by the mediastinum that contains the heart, esophagus, thymus gland, and parts of other organs. Each lung is covered with a pleural membrane, the visceral pleura, and the parietal pleura. The space between the two pleura is the pleural cavity and is filled with a fluid that reduces friction between the two pleura during breathing. The pleural cavity is engulmed by pulmonary alveolar macrophages. The effective surface area of the alveoli is about 70 m².

2.6 Breathing

Pulmonary ventilation is the movement of air in and out of the lungs. Breathing in is inspiration or inhalation. Breathing out is expiration or exhalation. During inhalation the diaphragm contracts and flattens the thoracic cavity, causing the space within each lung to increase. This causes a partial vacuum causing air to rush in to equalize inside and outside pressures. Exhalation occurs when the diaphragm and intercostal muscles relax, allowing the elastic tissues to recoil and the thoracic cavity to decrease in size. Air is pushed out of the lung until the inside and outside pressures are again equal. Not all the air is pushed out of the lungs since the pleural cavity fluid is maintained at a pressure lower than atmospheric.

2.7 Gas/Vapor Exchange

The circulatory system delivers oxygenated blood to target organs and tissues, and delivers back blood saturated with CO₂ for exhalation. Each gas diffuses through the thin lining of the capillary and the thin lining of the alveolus. The usual concentration of O₂ in inhaled air is about 20.9% (v/v), and in exhaled alveolar air is about 14%. Similarly, the concentration of CO₂ is 0.040% (or 400 ppmv (parts per million by volume)), and 5.0–5.6%, respectively. The concentration of N₂ in both remains approximately constant at about 79%, as does argon concentration at 0.9% (9000 ppmv). The relative humidity (RH) of exhaled alveolar air is close to 100% or about 6.5% of alveolar air volume.

Thus mixed exhaled air and end-exhaled air can be distinguished on the basis of CO₂ and water vapor concentrations. It has been suggested that alveolar air concentrations of analytes be normalized to 5% CO₂ as denominator for comparison purposes, just as creatinine or specific gravity is utilized for urine analyte concentrations to correct for dilution effects. A water vapor criterion is impractical because of great variation of relative humidities in ambient air.

The above implies that vapors and gases of xenobiotics will also be absorbed adventitiously into the blood by diffusion, and will be similarly exhaled. The blood air partition coefficient \( K_{ba} \) at equilibrium at 37 °C is defined for an analyte of equilibrium concentrations \( c_{\text{blood}} \) and \( c_{\text{air}} \) in Equation (1) as:

\[ K_{ba} = \frac{c_{\text{blood}}}{c_{\text{air}}} \]  

If \( K_{ba} < 5 \), alveolar air does not reflect mixed venous blood analyte concentration.

The inverse of \( K_{ba} \) determines analyte alveolar breath concentration after analyte absorption, but is not the same as the dimensionless Henry’s law constant \( K_{H} \) for an analyte in air/water at 25 °C (Equation 2), though the two are related:

\[ K_{H} = K_{aw} = \frac{c_{\text{air}}}{c_{\text{water}}} \]  

Thus compounds that can be exhaled in the gaseous state must be gases, or the vapors of volatile liquids or solids with high vapor pressures.

Other characteristics propitious for breath monitoring for exposing analytes include:

- little potential for metabolism, for example, most anesthetics, aliphatic amines, and chlorofluorohydrocarbons;
- low blood and water solubilities, Equations (1) and (2), respectively:
• a low fat/blood partition coefficient $K_{fb}$ defined in Equation (3):

$$K_{fb} = \frac{c_{fat}}{c_{blood}}$$ (3)

$K_{fb}$ is related\(^{1}\) to the octanol/water partition coefficient $K_{ow}$ for chlorinated/brominated hydrocarbons and unsubstituted hydrocarbons by Equation (4):

$$K_{fb} = 70.9 \log K_{ow} - 127$$ (4)

for compounds of log $K_{ow} > 2.0$. The relationship of analyte $K_{ow}$ to its water solubility $c_{water}$ in micromolar units at 20–25°C is provided\(^{4}\) in Equation (5):

$$\log K_{ow} = 5.00 - 0.670 \log c_{water}$$ (5)

for compounds with log $K_{ow}$ over the range 1.0–6.7.

For example, the relatively inert chemical perchloroethylene at 25°C has the following measured characteristics:\(^{1}\) log $K_{ow} = 2.60$, $c_{water} = 2.413$ mM; and vapor pressure = 2.53 kPa corresponding to a $c_{air}$ of 19/(0.08205 × 298 × 760) = 1 mmol L\(^{-1}\), assuming an ideal gas. At 37°C, the $K_{fb}$ is (1.0–1.5) × 10\(^3\), and $K_{fb}$ is 9–15. Since perchloroethylene is not much metabolized (1–3%), breath analysis might be potentially useful, sensitive, and selective.

The calculated $K_{H}$ at 25°C from Equation (2) is 1/2.413 = 0.414 compared with the 1/$K_{ba}$ range of 0.067–0.11 at 37°C. This shows that the solubility of the analyte in blood is at least four times that in water, though the temperatures are different. The calculated log $K_{ow}$ using Equation (5) is 2.73. The measured value is 2.60, a positive bias of 5.0% using the log scale, but one of 35% using transformed values. The calculated $K_{fb}$ from Equation (4) using the measured $K_{ow}$ is 57, compared with the theoretical value of $K_{fb} = 67–167$, not far from the lowest part of the range. Thus most of the estimates are within an order of magnitude of measured values.

### 2.8 Reference Breathing Parameters

The lung volumes breathed in and out are dependent on physical activity, height, age, gender, and ethnicity, and show large interindividual differences. Volumes are all corrected to body temperature, body pressure, and saturated water vapor. These volumes must be measured before interpretation of breath concentrations can be made.

The vital capacity (VC) of the lung is the difference in volume between the total lung volume and the dead space (residual volume) without forcing exhalation. The dead space is the volume occupied by the nasal and oral cavities, larynx, trachea, and bronchi. The greater the physical activity the greater is the air volume breathed in and out for a given person. VC within a specific ethnic group for the same age increases linearly with increasing height.\(^{5}\) For a given height for adult men of the same age, the order of decreasing VC is: Swedes, other Europeans, African-Americans, and Indians/Chinese/Bantu/Other Africans.\(^{5}\) For example for 40-year-old males of 170 cm height, the average VCs were respectively in liters: 5.0, 4.2–4.3, 4.1 and 3.35–3.80.\(^{5}\) Thus people with smaller lung VCs who are of the same age and height but are of different ethnicity will show higher mixed exhaled breath concentrations than those with higher VCs after exposure to the same air concentration of analyte, or to the same absorbed dose. For males of the same height and ethnicity, VCs decrease with increasing age after adolescence. Weight does not affect VC much because of the competing effects of fat deposition and a large frame. Women have smaller VCs than men of the same height, age, and ethnicity. The threshold for a significant effect on VC is 10% of baseline.\(^{5}\) The forced expired volume in 1 s, (FEV\(_1\)), is the most widely used pulmonary function test because it is short, easily performed, and highly reproducible. The threshold for a significant effect on FEV\(_1\) is a 20% change in baseline.\(^{5}\) The FEV\(_1\)/FVC ratio is also often used, where FVC is the forced vital capacity. Most Caucasian male adults doing light physical activity breathe about 12–20 times per minute, about 20,000 times per day, and inhale about 35 pounds (13.4 m\(^3\)) of dry air per day.\(^{3}\) Each breath therefore has an average volume of about 672 mL.

The major predictive equations for males and females are known for Caucasians.\(^{8}\)

For males ≥ 18 years of age, for height $h$ in inches, age $a$ in years and volumes in L Equations (6–8) give:

$$VC = 0.113h - 0.032a - 1.86$$ (6)

$$FVC = 0.148h - 0.025a - 4.241$$ (7)

$$FEV_1 = 0.092h - 0.032a - 1.26$$ (8)

For Caucasian males < 18 years of age, for $h$ in inches, Equations (9) and (10) give:

$$VC = FVC = 4.4 \times 10^{-6} h^{2.6727}$$ (9)

$$FEV_1 = 0.86 VC$$ (10)

For Caucasian females ≥ 18 years of age, for $h$ in inches, Equations (11–13) give:

$$VC = 0.1h - 0.012a - 2.8$$ (11)

$$FVC = 0.115h - 0.024a - 2.852$$ (12)

$$FEV_1 = 0.089h - 0.025a - 1.932$$ (13)
For Caucasian females < 18 years of age, for h in cm
Equations (14) and (15) give:

\[ VC = FVC = 3.3 \times 10^{-6} h^{2.7194} \quad (14) \]
\[ FEV_1 = 0.86 VC \quad (15) \]

Both VC and FEV\(_1\) decrease during metal fume fever, and during acute exposures to toluene diisocyanate, red cedar dust, detergent enzymes, tobacco smoke, and formaldehyde.\(^9\)

Exhaled breath samples are generally taken voluntarily from sitting adults at rest for a set time of 10 s for each breath sampled, except in exercise physiology or kinesiology. The average dead space volume in Caucasian adults is about 150 mL.\(^1\)\(^6\) This volume is 30% (range 20–40%) of the total tidal volume of average volume 500 mL (400–600 mL range). Thus for the case of an analyte excreted in the breath from the blood, the highest concentration of analyte is in the alveolar air, assuming no analyte is breathed in. To ensure the absence of the analyte in room air where the exhaled breath is being taken, some investigators provide pure air for inspiration by valved respirators connected to compressed air before collection of each exhaled breath. This procedure is highly recommended, though it could also be done more conveniently by inspiring pure air contained in a gas bag.

When the dead volume and alveolar air are both sampled, this is termed “mixed exhaled air”. When the dead space is expelled and only alveolar air is sampled, this is termed “end-exhaled air”. Correspondingly, if the analyte is being breathed in and is chemically inert, the highest concentration is found in the dead space, and the most dilute in alveolar air assuming no excretion of analyte from the blood.

Thus, the interpretation of the concentration of analyte found in breath samples in addition to volume-dependent variables depends on:

- past history of exposure;
- whether high physical activity is involved or not if the major exposure was by inhalation;
- when the last inhalation exposure occurred;
- type of analyte; if the latter is reactive (for example 2,4-toluene diisocyanate and phosphine) or very water soluble (for example formaldehyde and methanol), breath concentrations are not interpreted simply;
- smoking history; the heavier the smoker of the same age, height, and ethnicity, the lower the VC. The average smoker loses VC at the rate of 50 mL year\(^{-1}\);
- medical conditions; the following lower VC: acute or chronic obstructive lung disease, asbestosis (lung damage caused by exposure to asbestos), asthma, berylliosis (lung damage caused by beryllium exposure), bronchitis, byssinosis (lung damage caused by cotton dust and microbial exposure), emphysema, fibroses, interstitial lung disease, lung cancer, lung allergy, pleurisy, pneumoconioses, pneumonia, pneumothorax, pulmonary edema, rhinitis, sarcoidosis, silicosis (lung damage caused by silica exposure), and tuberculosi. Hypertension raises VC;
- medications; use of bronchodilators (like methylxanthines, \(\beta\)-agonists, and anticholinergics) and bronchoconstrictors (such as histamine or methacholine) affect VC and the dead space volume.

3 BREATH

3.1 Gross Chemical Composition of Exhaled Breath

Table 1 shows the major compounds in expired breath apart from the inhaled components of pure air, methane, and hydrogen. The compounds are mostly gases and

These compounds occurred in at least seven out of 10 samples from eight volunteers not overly exposed to xenobiotic vapors and gases. Other compounds detected less frequently included: acetaldehyde (75-07-0), 2-butene (590-18-1) and trans (624-64-6), \(n\)-butyl alcohol (71-36-3), caprylic alcohol (111-87-5), carbon disulfide (75-15-0), cyclohexyl alcohol (108-93-0), dimethyl disulfide (624-92-0), ethyl acetate (141-78-6), ethyl acetylene (503-17-3), ethylene (74-85-1), 1-hexene (592-41-6), 2-hexene (592-43-8), isobutyl alcohol (78-83-1), methanol (67-56-1), methyl acetylene (74-99-7), methyl cyclohexane (108-87-2), methyl cyclopentane (96-37-7), 1-octene (629-05-0), 1-pentene (109-67-1), propane (74-98-6), and \(n\)-propyl alcohol (71-23-8).
vapors from the metabolic processes of the body or those emitted by symbiotic microorganisms.

The products of mammalian metabolism include:

- the volatile ketone body acetone (fruity smell of odor threshold about 400 ppbv (parts per billion by volume)\(^{4}\)) when fat breakdown predominates, or in diabetes. Breath concentrations in excess of 2 ppbv have been measured;
- isoprene from the dephosphorylation of isopentenyl pyrophosphate and dimethylallyl pyrophosphate, and during the synthesis of geranyl (farnesyl) pyrophosphate during the synthesis of squalene in the cholesterol biosynthetic pathway;
- excess aldehydes like acetaldehyde (odor threshold about 4 ppbv\(^{4}\)) released from transketolase activated aldehyde transfers. Biological oxidation processes via cytochrome- P450 produce formaldehyde, acetaldehyde, acetone, propanal, 2-butanone, \(n\)-butanal, \(n\)-pentanal, and \(n\)-hexanal in human breath,\(^{12}\) as well as acetone, 2-butanone, 2-pentanone, 2-hexanone, and 2-heptanone in rat breath.\(^{13}\) Cytochrome 2E1 is largely responsible for the formation of short chain methyl ketones in rats;\(^{13}\)
- nonmethane alkanes like ethane (odor threshold about 12 ppbv\(^{4}\)) from \(n\)-3 polyunsaturated fatty acids, \(n\)-butane from \(n\)-5 polyunsaturated fatty acids, \(n\)-pentane\(^{11}\) (odor threshold about 2 ppbv) from \(n\)-6 polyunsaturated fatty acids, and \(n\)-hexane from \(n\)-7 polyunsaturated fatty acids by lipid peroxidation starting from the methyl end of the fatty acid. Unsaturated aliphatic hydrocarbons except for acetylene are also produced by lipid peroxidation.

Those compounds emitted by symbiotic microorganisms include:

- acetaldehyde from the decarboxylation of pyruvate from glycolysis to form acetaldehyde, and its further reduction product ethanol from fungi, this process being in competition with L-lactate formation;
- sulfides and disulfides from anaerobic bacteria. Dimethyl sulfide has an odor threshold of about 200 pptv (parts per trillion by volume);\(^{14}\)
- acetylene from anaerobic bacteria, along with methane and hydrogen.

Ethanol and acetaldehyde could be of both metabolic, microbial, or xenobiotic origin. The origins of dimethyl-difluorosilane, indene, and furan are unknown. For chromatographic analyses of xenobiotics, the background peaks must not interfere with analytes of interest. Other endogenous compounds have been found including hydrogen cyanide from the oxidation of thiocyanate by salivary peroxidase,\(^{4}\) and nitric oxide formed mostly from the endothelial cells in the nasal cavity (0.750–1.60 ppm).\(^{15}\) Breath also contains particles up to 4 particles cm\(^{-3}\), usually below 300 nm aerodynamic diameter, with \(<\)2% of the particles being of diameter \(\geq 1 \mu\text{m}\).\(^{16}\) The proportion of particles increases with increasing physical activity. Particulate matter and excess water are usually caught in an empty impinger just before the sampling device.

### 3.2 Markers of Xenobiotic Exposure in Exhaled Breath

The major set of recommendations for xenobiotics in breath in the United States are the BEIs of ACGIH provided in Table 2.\(^{17}\) They are all used for exposing xenobiotics rather than their metabolic progeny. The breath BEIs are the biological equivalent values after absorption of their corresponding threshold limit values (TLV) for workplace physical activity. The TLV is the time-weighted average air concentration in the personal

breathing zone samples that are taken for 8 h per work day over 5 d per week over a working lifetime that is deemed nontoxic. The BEIs measure the excretion of markers of inhaled absorbed chemicals during a workshift. BEIs do not account for nonwork exposures, or workplace skin or oral absorption.

The distinction between excretion of absorbed marker and exhalation of inhaled chemical is better distinguished with end-exhaled air samples than with mixed exhaled air samples. Thus the BEI breath recommendations are for the use of the former. However when the marker of absorbed dose is the same as the inhaled compound, it is still possible that what is being measured in the breath is the last high exposure or the most recent exposure rather than excretion of the marker. Thus direct reading instrument air concentration measurement should be done to define the last inhalation exposure. This is not common practice, however. The problem does not arise when the marker is different from the inhaled compound, or if only oral or skin absorption of the exposing compound is definitely involved. Breathing in pure air only has been the solution adopted by some investigators.

The breath studies of the TEAM studies of EPA have been reviewed. Breath samples were taken after 12 h of exposure, the previous 12 h being monitored by breathing zone personal sampling (the sampler was located on the lapel with the pump for the solid sorbent located on the belt). The increased exposure to benzene and styrene for smokers was first proven in these studies. Chamber studies involving 10 h exposures at parts per billion by volume concentrations followed by 24 h breath excretion for humans were also done.

The data were analyzed by a four-compartment model. Representative compounds were chosen for study. The fractions of the absorbed dose excreted in the breath at equilibrium were nonpolar aromatics and n-decane, 0.06–0.16; chlorinated aliphatics (trichloroethylene and dichloromethane), 0.22–0.23; n-hexane, 0.35; and methyl chloroform, 0.88.

Breath acetone also arises from the metabolism of isopropyl alcohol, and from the metabolism of C1 and C2 halogenated compounds.

Breath 2,2,2-trichloroethanol can arise from metabolism of methyl chloroform, trichloroethylene, and perchloroethylene as well as from trichloroethanol exposure. Since methyl chloroform and perchloroethylene are not much metabolized, the major interference is from trichloroethylene. The pulmonary fLo.5 (the breath half-time) also differ.

Smoking is a major contributor to breath concentrations of over 6000 chemicals. Important ones are benzene, CO, ethylene oxide, and styrene.

The following metal markers can be analyzed in breath:

- Mercury: mercury vapor is 74–80% absorbed after inhalation and has been detected in exhaled breath for a few hours after the end of exposure. The excretion half-times in breath are 1 min, and 18 h. Mercury vapor has been detected in the mouth and from exhaled air from mercury amalgam tooth fillings. Mercury is also liberated by metabolism of aryl and alkoxyalkyl mercury derivatives.
- Hydrides: metal hydrides such as arsine, hydrogen mercuride, hydrogen selenide, stannane, stibine, plumbane, and hydrogen telluride should be amenable for detection in breath after exposure to the hydride. Hydrogen selenide has been detected in breath.
- Alkylated metal derivatives: the alkyl derivatives of lead and mercury are also probably partially eliminated in the exhaled breath after inhalation, although this has not been specifically shown. Dimethylmercury may also be exhaled after endogenous formation. Dimethylselenide is excreted in exhaled breath at high selenium absorbed doses. Dimethyl telluride (garlicky odor) is similarly excreted.
- Other covalent metal species: some examples may include include beryllium chloride and probably stable volatile metal esters.

3.3 Medical Breath Testing

There is an extensive literature. Some reviews and experimental studies are cited in Table 4, which gives details of the current uses of medical breath testing. These tests are particularly important for children, and where

\(a\) Some data are from ACGIH\(^{6}\) for lung retention (RT), breath excretion after absorption (EX), and breath half-time \(t_{0.5}\), after exposure to the time-weighted average concentration (TWA) for 8 h.

The use of compounds with radioactive labels previously inhibited the common use of labeled CO\(_2\) tests. Explosive growth is now occurring in this research area with the advent of \(^{13}\)C-enriched commercial substrates, the common use of gas chromatography/mass spectrometry (GC/MS), and the lack of human subject and human fears about radiolabeled compounds.\(^{44}\)

### 3.4 Dental Breath Tests

A major use of breath tests is to define the sources of halitosis (bad breath or malodor). The dental breath...

tests concentrate on odors from the mouth, the tongue, the oropharynx, the teeth, and the gums. Bacterial activity in the oral cavity is the usual reason for mouth odor. The bacterial culprits are usually Gram-negative, but especially Klebsiella spp and Enterobacter spp. Volatile sulfides and disulfides, cadaverine, putresine, hydrogen sulfide, and volatile acids have been postulated as the odoriferous agents. The most effective treatments are by use of zinc acetate impregnated chewing gums which inhibit thiol compound emissions, effective mouth hygiene that controls plaque, and mouth washing with chlorhexidine gluconate which is a bactericide.

4 BREATH SAMPLING

Breath analysis can be direct or a sample of breath enclosed in a container can be taken for laboratory analysis. The direct approach saves time but is more expensive. The container must be large enough to enable sensitive detection of the analyte, the instrumental detection limit being exceeded by increasing sample and subsampling sizes. The more sensitive the analyzer the more likely that it can be used for direct measurement without intermediate containers. Another alternative is to concentrate breath directly or from the breath sample container by using a solid sorbent or impinger technique before later laboratory analysis.

4.1 Gas Bags

Many breath samples are collected in clean nonleaking Tedlar™ or Teflon™ gas bags equipped with an open/shut valve of stainless steel or Teflon™, and a separate or an integrated injection valve suitable for using gastight syringe subsampling and also injection of liquids to generate defined concentration atmospheres. An evaluation of 1-L Tedlar™ bags in containing a typical 500 mL single-breath sample has been published. The bags contained separately acetone, 2-butanol, methanol, methyl chloroform, perchloroethylene, and m-xylene in either an atmosphere of saturated water vapor, or dry nitrogen. No significant difference occurred at $p \leq 0.05$ for each compound except for methanol, where the wet-bag reading was 10% lower than the dry bag. When excess water was present beyond three times saturation, acetone and 2-butanol also gave lower wet bag readings. Concentrations of many organic compounds and mixtures in Tedlar bags have also been shown to provide the same responses to detectors not sensitive to water vapor at 90% RH and dry conditions.

A typical breath sampling set-up consists of the bag connected to an impinger or Buchner flask that catches spittle and drool. All connections must be of clean Teflon™ tubing of minimum length and diameter wide enough to minimize resistance. The sterilized mouthpiece that is connected to the impinger or Buchner flask must be able to fit into the pursed lips for air blowing purposes. The
total possible volume of the bag should be chosen so that the bag is at least half-filled with breath sample. The bag should never be completely full since this promotes leaks at seams. During injection or subsampling the analyst must be careful not to puncture the bag walls opposite the injection or subsampling port. The gas bag technique is favored by field industrial hygienists, but has also been used by clinicians to sample for hydrogen, nitrous oxide, and other gases. The gas-tight syringe mode of introduction to the analyzer minimizes any matrix effects of breath since the air constituents elute first.

4.2 Summa Cannisters

Summa cannisters are stainless steel cannisters which can be evacuated. The stainless steel interior is relatively inert and some cannisters are also coated inside with Teflon. Some disadvantages relative to Tedlar gas bags are their weight, greater expense for the same volume, being opaque, and leaking often at their on/off valves. The non-Teflon coated models are more prone to corrosion and analyte adsorption/desorption cycles.

The Summa cannister technique is favored by many samplers, including during EPA’s TEAM studies. Some recent examples include:

- sampling of methyl tertiary butyl ether (MTBE) in gasoline stations;
- sampling of vinyl chloride, cis-1,2-dichloroethene, chloroform, bromodichloromethane, and trichloroethylene.

4.3 Solid Sorbent Sampling

This is probably the major mode of sampling of vapors because of its low weight and better storage and transport characteristics. The concentrated analyte has to be stored and transported, rather than the breath sample itself. There are two general modes: physical adsorption and chemisorption. Both forms are amenable to thermal desorption for maximum sensitivity, or solvent desorption at high concentrations and long sampling times. Subsequent thermal desorption also minimizes any matrix effects of breath. However, the solid sorbent must be thermally conditioned beforehand. Solvent desorption will cause masking of breath constituents where the solvent and its impurities elute on chromatographic columns. Since a fraction of the sample is injected on-column, its sensitivity is less than thermal desorption techniques.

Some recent examples of physical adsorption of breath compounds include:

- 1259 breath VOCs
- Ethanol, acetone, and isoprene
- VOCs in microgravity
- Benzene

A recent example of chemisorption of breath compounds involved the reaction of aldehydes and ketones with 2,4-dinitrophenylhydrazine coated on silica gel. These techniques can be used directly by blowing through the solid sorbent tube connected to a dry gas meter to record the volume, or after collection of breath in a container where the breath can be subsampled at a constant flow rate for a given time. The solid sorbents must be able to tolerate high relative humidities. Thus solid sorbents like Tenax TA, XAD resins, and Chromosorb porous polymers are favored for both physical adsorption and chemisorption.

4.4 Glass Tubes

Though these are not favored because of their fragility, 40 mL glass tubes equipped with Teflon stopcocks and stoppers, and silanized to prevent wall adsorption have been used to contain breath samples containing methyl chloroform, carbon tetrachloride, and trichloroethylene vapors. Glass tubes have the advantage of being evacuable and transparent.

4.5 Other Methods

There are many other breath collection methods. Analyte impinger collection is usually not done because the contents are spilled easily in the field, on storage, and during transport. Impingers are also fragile. A cheap homemade device has captured breath samples containing chloroform and allows transfer to an evacuated headspace vial for subsequent analysis. Cannulas connected to direct reading instruments have been inserted into the nose for sampling purposes, but this is invasive. Another device also allows thermal desorption. Cryogenic concentration has been reported to concentrate inflammation mediators and was used initially in the field. Thorium and radon progeny have been collected on double filter cassettes.

5 CHEMICAL ANALYSIS OF BREATH

5.1 Introduction

There are two types of analysis:

- those for single analytes involving chromatographic or very selective methods
- those for a class of analytes, for example, direct reading methods.
As for the analysis of single VOCs in other branches of chemistry, capillary GC/MS is the gold standard, followed by capillary gas chromatography/Fourier transform infrared spectrometry (GC/FT/IR). Capillary and packed column GC/detection are screening techniques that provide maximum breath concentrations. High-performance liquid chromatography (HPLC) methods are rare except for the 2,4-dinitrophenylhydrazones of aldehydes and ketones and, although an ultraviolet detector is used, specificity is conferred by the selectivity of the derivatization.\(^\text{(63)}\) Direct reading methods are useful screening techniques that may signal the need for a second look at breath sampling with single compound analysis. However, sensitivity and selectivity may be major problems with direct reading methods.

### 5.2 Gas Chromatography and Mass Spectrometry Methods

GC/MS has been used to identify, quantify, and confirm most of the VOCs in breath beginning in the early 1970s.\(^\text{(10,69)}\) The early work was done on packed GC columns and used magnetic sector mass spectrometers.\(^\text{(10)}\) Most of the recent work utilizes capillary GC and quadrupole or ion trap MS (mass spectrometry). Table 1 summarizes the major analytes quantified and confirmed by GC/MS.\(^\text{(10)}\)

Among selected breath components quantified and confirmed by capillary GC/MS within the last five years are the following:

- organic solvents in the breaths of workers\(^\text{(10,66,70)}\)
- organic solvents in the breaths of home dwellers or in the ambient environment\(^\text{(18,19,21,56–59,71)}\)
- Endogenous VOCs;\(^\text{(11,31,59,60)}\) the most sophisticated of these studies\(^\text{(59)}\) involves adsorption of exhaled breath on a solid sorbent, thermal desorption into a cryotrap, and then a second thermal desorption into the GC/MS. Multivariate techniques allowed identification of patients having characteristic breath volatiles (large concentrations of n-pentane and carbon disulfide) for schizophrenia\(^\text{(72)}\)
- \(^{13}\text{CO}_2\) from \(^{13}\text{C}\)-labeled metabolism studies (see references 35–39, 41–44)
- organic solvents in the breaths of volunteers exposed to known solvents in chamber studies or after internal injection.\(^\text{(71)}\)

As expected, screening breath analysis has been done with detectors less expensive than MS. The breath concentrations so found are maximal ones and are not confirmed.\(^\text{(62,64,65,73)}\) This is not so if a solvent of known purity is exposed to volunteers in chamber studies, or after internally provided doses of pure solvents.\(^\text{(65,71)}\)

#### 5.2.1 The Selected Ion Flow Tube Method

A major new variation of the MS technique that is direct reading is the selected ion flow tube (SIFT) technique.\(^\text{(74–78)}\) The breath trace gases but not the major gases in air and breath are subjected to chemical ionization by ion–molecule reactions using “soft” proton transfer from preselected ions (\(\text{H}_3\text{O}^+, \text{NO}^+, \text{and} \text{O}_2^+\)) in a fast flow of inert carrier gas. The sensitivity for most endogenous compounds is about 10 ppbv. The time response is 20 ms, allowing concentration changes to be followed during a normal breathing cycle. Compounds such as acetone, nitric oxide, nitrogen dioxide, ammonia, isopropene, and methanol can be analyzed simultaneously directly or from gas bags without a GC column. The concentration of NH\(_3\) was shown to be proportional to the infection of \(\text{Helicobacter pylori}\),\(^\text{(76)}\) usually measured through labeled CO\(_2\) produced from the urease metabolism of labeled urea (section 3.3). The breath concentration of ammonia also increased ten times during kidney failure and the effectiveness of dialysis treatment can be determined by monitoring ammonia.\(^\text{(77)}\) Isopropene concentration increased during stress.\(^\text{(77)}\) The volatiles of tobacco smoke, crushed garlic, and masticated mint were also detected in breath samples.\(^\text{(78)}\) Breath concentrations of \(n\)-butylamine (fishy odor) and other amines were also correlated to kidney problems.\(^\text{(77)}\) The SIFT technique was able to quantify a mixture of eight chemicals of different MW in 20 ms without a column.\(^\text{(78)}\) The response vs concentration curves were linear from 10 ppbv to 30 ppbv. The technique is being miniaturized to make it portable.\(^\text{(77,78)}\) It cannot resolve isomers like those of xylene. It may not resolve low MW compounds when higher MW compounds are also present that can give rise to ions of the same \(m/z\) (mass-to-charge ratio).

Another GC/MS avenue for breath sampling is to use the only commercially available portable direct reading GC/MS, the Hapsite.\(^\text{(79)}\) No such uses have been reported.

### 5.3 Infrared Methods

FT/IR methods have been used to analyze some breath organics and CO\(_2\). An example is the analysis of methanol in the end-exhaled breath collected in a Mylar gas bag after inhalation of 0, 100, 200, 400, and 800 ppbv, and after dermal exposure by immersing one hand in the pure solvent.\(^\text{(80)}\) The spectrometer was equipped with a mercury–cadmium-telluride nitrogen-cooled detector. The detection limits were 500 ppb for methanol and 2000 ppm for CO\(_2\). The concentration of methanol...
in end-exhaled air did not become proportional to blood methanol concentration until 2 h after each 8 h inhalation exposure ended. Methanol peaked in the breath 15 min after a 16 min dermal exposure of one hand. The headspace GC/flame ionization detection (FID) technique for measuring methanol in blood may have been suspect in this study.

Direct reading infrared (IR) methods are utilized directly on breath or breath in gas bags for quantitation of CO₂ by capnometers,¹,²,²⁸,⁸¹ and ethyl alcohol by the standard Intoxilyzer 5000S instrument.⁸²⁻⁸⁵ Any compounds that absorb at the same wavelength as the analyte are positive interferences. Thus, for breath alcohol using the Intoxilyzer 5000S, the endogenously produced acetone, isopropyl alcohol, and methyl ethyl ketone all interfere as shown by parallel GC headspace analysis.⁸² Solvent vapors that may interfere at high concentrations are toluene, n-xylene, o-xylene, methanol, and isopropyl alcohol.⁸⁵

5.4 Other Methods
Nitric oxide is detected by a portable chemiluminescence detector.¹⁵,⁵⁴,⁸¹ Portable direct reading electrochemical detectors have been used to detect breath ethyl alcohol,⁸⁴ and carbon monoxide.⁵³,⁸⁶ The volatile mouth total thiols and disulfides thought to be responsible for halitosis can be measured directly by a halimeter.⁴⁸,⁴⁹ Gamma counting is used to detect exhaled thorium collected on filters.⁶⁸ Colorimetric detector tubes can be used for specific gases.⁸⁷ The accuracy of the latter is ±25% and the interferences must be tested for separately.

Gases of high concentration such as hydrogen,⁵⁵ methane, oxygen, nitrogen, argon, water vapor, and carbon dioxide can be quantified in the same sample by the standard method of GC/thermal conductivity detection using molecular sieve or porous-layer open tubular columns.⁸⁸

1 INTRODUCTION

PIGE or prompt radiation analysis (PRA) is an analytical technique making use of γ-rays that are emitted during or immediately after bombardment of a sample with an ion beam. Here, discussion is restricted to prompt γ-ray emission. These are γ-rays that are detected during irradiation, in contrast to activation techniques where radiation is detected after irradiation. The technique has been used since the 1960s for analytical purposes. Sippel and Glover showed that PIGE with protons could be used for the determination of Mg and F in geological samples. Pierce et al. showed that deuterons could be used to determine C and Pierce et al. used 4 MeV protons to determine the amount of Si in several kinds of steel. At that time, the detection of γ-rays was mostly performed with NaI(Tl) detectors which have a relatively poor energy resolution, thereby limiting the analytical technique to the determination of one or two elements simultaneously. The development of Ge(Li) detectors with a much better energy resolution around 1970 made it possible to determine a number of elements in the sample simultaneously. Since then, studies have been carried out with light as well as heavy projectiles that showed that PIGE with a Ge(Li) detector is a powerful and sensitive method of multielemental analysis. In general, protons and α-particles are used as projectiles, but measurements have also been done with d, t, 3He, Li, B, N, F and Cl projectiles. Besides the determination of concentrations in (thick) samples, PIGE can also be used to determine depth profiles by using narrow resonances in a cross-section of nuclear reactions. In general, PIGE is a technique that is less often used than other ion-beam analysis techniques like particle-induced X-ray emission (PIXE) or Rutherford backscattering spectroscopy (RBS). In PIXE or RBS spectra, elements appear in a relatively simple and systematic way, making interpretation and analysis of the spectra straightforward. In PIGE, the situation is more complex since even different isotopes of the same element result in completely different γ-spectra. Knowledge about the energy of resonances, the energy of the γ-rays, and interfering reactions in the sample must be available for each nuclide of interest. Interpretation and analysis of PIGE spectra can thus be much more complex than for PIXE or RBS spectra. This means that PIXE and RBS can be seen as general techniques to determine the composition of an unknown sample, while PIGE is used when the composition of the sample is more or less known and a γ-spectrum can be used to quantify the concentration or determine a concentration profile. PIXE (see PIXE (Particle-induced X-ray Emission)) is a technique that is generally used to determine elements.
with \( Z > 12 \). PIGE is often used as a complementary technique to PIXE to determine light elements.

Although PIGE is regarded as a less general and versatile technique compared to PIXE, PIGE can have strong advantages. This is particularly the case for light elements \( (Z < 11) \) that cannot be analyzed or are hard to analyze with PIXE. Moreover, PIGE produces totally different spectra for elements of neighboring \( Z \), removing peak-overlap problems between neighboring elements in the spectra. PIGE is only sensitive to specific isotopes, limiting the general applicability. It is, however, a powerful tool when isotopic analysis is required. Also, compared to similar PIXE spectra, minimal pile-up problems are present in PIGE spectra when there is no significant background radiation. Although PIGE is typically less sensitive than PIXE, the peaks in a PIGE spectrum are well separated and there is no need for absorption corrections for the \( \gamma \)-rays leaving the sample. This simplifies the experimental arrangement and the analysis of the spectra and can make the technique more attractive.

2 BASIC NUCLEAR PHYSICS

2.1 Principles of Nuclear Reactions

PIGE is based on nuclear reactions induced by accelerated beams that hit the sample of interest. After the reaction, nuclei in the sample remain in the excited states and decay by emitting \( \gamma \)-rays. The energies of these \( \gamma \)-rays are characteristic of the elements (isotopes). The two measured quantities thus yield the elemental identification and concentration, respectively. The technique is thus quantitative, or semi-quantitative when standards are used.

For a nuclear reaction to occur between a beam particle and a sample nucleus it is necessary that the beam energy exceeds the Coulomb barrier. The barrier energy (in MeV) can be estimated from Equations (1) and (2):

\[
E_c = 1.44 \frac{Z_1Z_2}{d} \\
\text{with } d = 1.25 \frac{A_1^{1/3} + A_2^{1/3}}{15 \text{ m}} \tag{2}
\]

where \( Z_1 \) and \( Z_2 \) are the proton numbers of the beam particles and the sample nucleus, respectively. The quantity \( d \) in fm \( (1 \text{ fm} = 10^{-13} \text{ m}) \) is approximately the sum of the two respective radii, with \( A_1 \) and \( A_2 \) the respective mass numbers. The approximation is based on the notion that nuclear forces have very short ranges (~1 fm). Thus the two colliding nuclei must almost touch each other. If the beam energy is smaller than \( E_c \), then the beam particle will be deflected by the nucleus. \( \gamma \)-Rays can still be produced in this case by Coulomb excitation of the nucleus. This, however, is not very likely for light ion beams and will not be discussed further because light-ion induced reactions will be treated as applying most frequently. These reactions encompass inelastic scattering, capture (or compound nuclear) reactions and particle transfer. For protons they are denoted as: \((p,p')\), \((p,\gamma)\) and, for instance, \((p,\alpha\gamma)\), respectively.

At low energy, \( <E_c\), only atomic excitations occur, giving rise to the emission of X-rays. This process is exploited in the PIXE method, as discussed in PIXE (Particle-induced X-ray Emission).

Equation (1) results in \( E_c = 1.2 \text{ MeV} \) for protons on \( ^{7}\text{Li}, 4 \text{ MeV on } ^{28}\text{Si}, 5.2 \text{ MeV on } ^{40}\text{Ca} \) and \( 13.6 \text{ MeV on } ^{208}\text{Pb} \). For \( \alpha \)-particles on \( ^{28}\text{Si} \), a beam energy of at least \( 7 \text{ MeV} \) is required. It is concluded that a proton beam energy of at least \( 1 \text{ MeV} \) is required and single-ended Van de Graaff accelerators, tandem Van de Graaff accelerators and cyclotrons are used for PIGE experiments.

The most commonly applied nuclear process in PIGE is the compound nuclear reaction, schematically written as Equation (3)

\[
a + A \longrightarrow C^* \longrightarrow B + b, \tag{3}
\]

with a representing the beam particle, \( A \) the target nucleus, \( C^* \) the compound nucleus (CN) in excited state that may decay by \( \gamma \)-rays or form a final product nucleus \( B \) and particle \( b \). The product nucleus \( B \), when formed in an excited state, \( B^* \), decays by \( \gamma \)-rays. The latter \( \gamma \)-rays are called reaction \( \gamma \)-rays, while those of \( C^* \) are \( \gamma \)-rays of the CN. Those \( \gamma \)-rays are characteristic of the sample nucleus \( A \) (see Figure 1), in particular from the well-known discrete low-lying states.

The CN model is based on the assumption that the probability of decay into any specific set of final products is independent of the means of formation of the CN. The decay of the CN level only depends on its energy. If the excitation energy is above the particle binding energy then it surely will decay via the particle channel, because particle decay, owing to its strong interaction, is much more likely than \( \gamma \)-ray decay with its electromagnetic interaction.

The excitation energy, \( E_x \), of the CN \( C^* \) can be calculated from Equations (4) and (5):

\[
E_x = Q + \frac{\text{E}p \text{m}_A}{m_A + m_a} \tag{4}
\]

\[
\text{with } Q = [m_C - (m_A + m_a)]c^2, \tag{5}
\]

with \( Q \) the reaction \( Q \) value in MeV, when the masses are expressed in atomic mass units, \( u \), and the speed of light squared as \( c^2 = 931.5 \text{ MeV}u^{-1} \). In exothermic reactions mass is converted into energy and \( Q \) is positive, while
in endothermic reactions \( Q \) is negative. In Equation (4) the laboratory beam energy \( E_p \) is corrected by the mass factor of the two initial particles to obtain the energy in the center-of-mass system as an internal energy. The external energy or kinetic energy, \( E_{\text{kin}} \), of the center-of-mass itself is written as Equation (6)

\[
E_{\text{kin}} = \frac{E_p m_a}{m_A + m_a}
\]

This energy is completely transferred to the recoiling CN as kinetic energy. The recoil energy may be of importance if the nuclear states involved in the decay of the CN have lifetimes shorter than the slowing down time of the recoil in the sample. In that case the \( \gamma \)-rays are emitted in flight and may show a shift and broadening in energy (see section 2.2).

Another important factor in PIGE analysis is the yield of \( \gamma \)-rays, which is directly connected to the reaction and emission probabilities. Here the reaction probability will be treated, while \( \gamma \)-ray emission is discussed in section 2.2.

The reaction probability is commonly expressed by the reaction cross-section \( \sigma \), which represents a fictive surface at the nucleus through which the initial particle has to penetrate to induce a particular reaction. In many cases the cross-section exhibits a resonance-like behavior as a function of beam energy (Breit–Wigner shape), such as in proton capture or \((p, \gamma)\) reactions at relatively low energy. The width \( \Gamma \) (in eV) of the resonance is a measure of the probability of forming that particular CN level and of decaying via \( \gamma \)-ray emission. The width \( \Gamma \) is related to the lifetime, \( \tau \), of the CN level via Equation (7), the uncertainty relation of Heisenberg:

\[
\Gamma \tau = \frac{\hbar}{2\pi}
\]

To distinguish the formation of the CN level from the decay probability, \( \Gamma_p \) is introduced as the formation width (or probability) and \( \Gamma_\gamma \) as the decay width. The reaction cross-section can then be expressed as a function of beam energy in Equation (8)

\[
\sigma_{p,\gamma}(E) = \frac{\Gamma_p \Gamma_\gamma}{(E - E_R) + \Gamma^2/4}
\]

Here \( E_R \) is the resonance energy at the maximum of the cross-section, \( \hbar \) is the reduced wavelength of the initial particle and \( g \) is a statistical factor, determined by the spins, \( I, j \) and \( J \) of the nuclear particles \( A, a, \) and \( C^* \), respectively, Equation (9):

\[
g = \frac{2J + 1}{(2j + 1)(2I + 1)}
\]

For details see Deconninck.(1) If the resolution of the beam is larger than the total width \( \Gamma \), the total area \( I_m \) under the resonance is obtained by integrating the cross-section over a broad energy range around the resonance, Equation (10):

\[
I_m = 2\pi \hbar^2 g \frac{\Gamma_p \Gamma_\gamma}{\Gamma}
\]

A Breit–Wigner resonance and its integral are shown in Figure 2.

Figure 1 Formation (a) of CN \( C^* \) in an excited state (CN level) (b) and its decay either by \( \gamma \)-rays or by particle emission (c) to form the reaction product \( B^* \) in excited states or in the ground state \( B \). In (b) resonance levels are indicated with their schematic cross-sections \( \sigma \). On the vertical axis the center-of-mass (c.m.) energy is indicated. (The figure is adapted from Deconninck.1/)}
In the case where \( \Gamma \) is small (keV) the factor \((2J + 1)\Gamma P / \Gamma \) is proportional to the integrated cross-section. Thus the factor is proportional to the sensitivity of the resonance reaction. The total width \( \Gamma \) is contained in several nuclear data tables for many resonance levels in nuclei. From this it can be concluded that the value of the cross-section is not only important for sensitivity, but also for knowledge of resonance structures (Equation 8) and, for practical applications, for the beam energy spread.

There are many other possible nuclear reactions yielding \( \gamma \)-rays that are resonant or nonresonant. Examples often used for elemental analysis are the inelastic scattering \((p,p'\gamma)\), and further \((p,\alpha\gamma)\) and \((p,n\gamma)\) with protons. With other beam particles, commonly used reactions are \((d,p\gamma)\), \((d,n\gamma)\) and \((\alpha,n\gamma)\). At relatively low beam energies, in the few meV range, the \((p,p'\gamma)\) and the \((p,\alpha\gamma)\) reactions also show resonant structures. Therefore Equation (8) can be used to find the cross-section by replacing \( \Gamma y \) for the exit channel by \( \Gamma p \) and \( \Gamma x \), respectively. In the cases where the cross-section does not show resonant behavior, but varies only slowly with beam energy, the cross-section can be taken to be constant or averaged over the relevant energy region.

For nonresonant reactions, Equation (11) can be used to calculate the \( \gamma \)-ray yield \( Y(E_0) \) at an incident energy \( E_0 \) of particle \( x \) on a target containing element \( A \) with atomic mass \( A \) (in g mol\(^{-1}\)), concentration \( c_A \) and with a cross-section \( \sigma_{x,\gamma}(E) \), according to Equation (8), to produce particular \( \gamma \)-rays:

\[
Y(E_0) = N_p c_A A^{-1} N_{av} e(E_0) \frac{\gamma}{4\pi} \int_{E_0}^{E_1} \frac{\sigma_{x,\gamma}(E)}{\varepsilon(E)} dE \tag{11}
\]

where \( N_p \) is the number of particles \( x \) hitting the target, which can be deduced from the measured beam current and time, \( N_{av} \) is the Avogadro number, \( e(E_0) \) is the efficiency of the detector for the particular \( \gamma \)-ray and \( \Omega \) is the solid angle of the detector (in steradians). The cross-section \( \sigma_{x,\gamma}(E) \) (cm\(^2\), note 1 barn \( = 10^{-24} \) cm\(^2\)) and the stopping cross-section \( \varepsilon(E) \) (MeV g\(^{-1}\) cm\(^2\)) are integrated over the energy from \( E_0 \) to \( E_1 \), the energy of the particle \( x \) when leaving the target at the back side. Equation (11) also represents the thick-target yield, by putting \( E_1 = 0 \), corresponding to the incident particle coming to a complete stop in the sample. The thick-target yield in literature is often expressed in units of \( \mu \text{C sr}^{-1} \), that is in counts per quantity of electric charge on the target and per unit of solid angle. This can be derived easily from Equation (11) by dividing out \( N_p \) (expressed as charge) and \( \Omega \). The cross-sections and the stopping cross-sections of particle \( x \) slowed down in the sample have been tabulated in various publications for many particles, energies and stopping materials (see e.g. Nuclear Data Tables\(^{12} \) for reaction cross-sections and Ziegler et al.\(^{13} \) for stopping powers). If they are not tabulated then the known values must be interpolated or, in the worse case, measured. In Equation (11) the attenuation of \( \gamma \)-rays in the target, in possible absorbers and in the detector window is neglected, but it must be taken into account when \( \gamma \)-ray energies are low.

For detailed formulas in cases of sharp and broad resonances the reader is referred to Deconninck.\(^{11} \) To circumvent the problems involved in the use of absolute cross-sections and stopping powers, internal or external standards are often used to compare with the measurement on the real sample. In the case where internal standard elements are added, their concentrations and cross-sections must be known precisely. In the case of an external standard, a sample is prepared with exactly the same elements as the sample of interest, at known concentrations. In the first case only one measurement is needed, but integrations for the different elements (Equation 11) are still necessary. However, beam current and detector solid angle are canceled. In the second case the integrations are canceled, but beam current (and solid angle, if different) need to be measured.

For thin samples the cross-section can be considered constant. It is convenient to add a standard element with mass number \( A_s \) and with known concentration \( c_s \) to the sample. When comparing the \( \gamma \)-ray yields of element \( A \) and standard \( S \), not only are the solid angles and number of beam particles canceled, but so too are the stopping powers because in both cases they are the same. The
unknown concentration \( c_A \) can easily be calculated from the measured \( \gamma \)-ray yields from Equation (12):

\[
c_A = c_s \frac{Y_A \sigma_{\gamma A} A_A}{Y_{\gamma} \Phi_{\gamma A} A_s}
\]  

(12)

### 2.2 \( \gamma \)-Ray Emission

\( \gamma \)-Ray emission is governed by the electromagnetic interaction and transitions are described by connecting the initial and final nuclear quantum states via the electromagnetic multipole operator. The electromagnetic field can be expanded in terms of multipoles, i.e. monopole, dipole, quadrupole, octupole, and so on. They can be of electric or magnetic character, with certain constraints. The multipole moments have the form of Equation (13):

\[
M_l \propto r^l Y^m_l(\theta, \phi)
\]  

(13)

here \( l \) represents the order of the multipole moment and \( Y^m_l(\theta, \phi) \) is the spherical harmonic function. The electromagnetic operator, which acts on the initial and final states involved and gives rise to the \( \gamma \)-ray transition, also has the basic form of Equation (13). For a detailed treatment of the electromagnetic features important for \( \gamma \)-ray emission the reader is referred to textbooks, for example by Krane\(^{(14)}\) and Ejiri and de Voigt.\(^{(15)}\) Here we will restrict ourselves to the more practical rules that determine the nature and intensity of \( \gamma \)-rays.

The electromagnetic transition probability \( T(E(M), l) \), according to Equation (7) is given by Equation (14):

\[
T(E(M), l, if) = \frac{\Gamma(E, (M), l, if)}{\hbar} = \frac{\Gamma_y}{\hbar} = \frac{1}{\tau}
\]  

(14)

The radiation width \( \Gamma_y \) of Equation (7) is thus equivalent to the transition probability \( T \), which depends on the electric \( (E) \) or magnetic \( (M) \) character, on the multipolarity \( l \) of the radiation and on the structure of the initial and final nuclear states \( (if) \). The multipolarity \( l \) of the transition corresponds to the order \( l \) of the multipole moment and of the multipole operator (Equation (13)). The transition probability depends on external factors, i.e. the energy \( E_y \) of the transition, the multipolarity \( l \) and the nuclear radius \( R \), as well as on the internal factors (i.e. the nuclear structure of the initial and final states). The latter information is not always available and varies strongly from nucleus to nucleus and even within a nucleus from state to state. Therefore we will discuss the general consequences of the external factors and refer the reader to the various nuclear data compilations for the internal factors; i.e. for nuclei with mass 21–44 to the compilation of Endt\(^{(10)}\) (and references quoted therein) and for nuclei below mass 21 to the compilation of Ajzenberg–Selove\(^{(11)}\) (and references quoted therein).

The importance of the external and internal factors is that they also determine the value of \( \Gamma_y \) and thereby the cross-section \( \sigma_{\gamma y} \), according to Equation (8) and thus the yield \( Y(E_\gamma) \), according to Equation (11). A simplified indication for the external factor \( T_{ex} \) can be obtained from Equations (15) and (16):

\[
T_{ex}(E) \propto \frac{E_y^{2l+1}}{\hbar c} R^{2l} 
\]  

(15)

and

\[
T_{ex}(M) \propto \frac{E_y^{2l+1}}{\hbar c} R^{2l-2} 
\]  

(16)

Noting that \( hc = 197 \text{ MeV fm} \), that \( E_y \) is of the order of 1 MeV and that the nuclear radius is about 3 fm for light nuclei, one concludes that the transition probability decreases rather strongly with increasing multipolarity of the radiation. For each unit of \( l \) the difference is about a factor of \( 10^4 \). The electric transitions are more probable than the magnetic ones of the same multipolarity by a factor of \( R^2 \), which is about a factor of 10 for light nuclei. Note that these are only rough estimates and that the internal factor may change the picture quite drastically. For instance in collectively rotating nuclei, in the strongly deformed regions, the electric quadrupole \( (E_2) \) transition is strongly enhanced. Nevertheless, it is probably safe to state that in general the sequence of probability for transitions to occur is \( E_1, M_1, E_2, M_2, E_3, M_3, E_4, M_4 \), and so on. The transition probability increases strongly with the transition energy, particularly for the higher multipoles. This is illustrated in Figure 3, where absolute transition probabilities are given for one-particle transitions, i.e. transitions caused by one (valence) proton in the nucleus.

The energy of the \( \gamma \)-ray is simply the energy difference between the initial and final states, Equation (17):

\[
E_y = E_i - E_f,
\]  

(17)

here \( E_i \) and \( E_f \) represent the excitation energies of the initial and the final states, respectively. In this formula the recoil energy of the de-exciting nucleus is neglected. It can be calculated from the \( \gamma \)-ray energy and mass, \( M \), of the nucleus as Equation (18):

\[
E_{rec} = \frac{E_y^2}{2Mc^2}
\]  

(18)

Noting that the numerator is of the order of megaelectron volts and the denominator of gigaelectron volts, \( E_{rec} \) is only about \( 10^{-2}E_y \), thus mostly of the order of kiloelectron volts, which can be neglected.

The multipolarity of the \( \gamma \)-radiation is restricted by the spins (and parities) of the initial and final states \( I_i, (\pi_i) \)
and $I_i (\pi_i)$, respectively. The multipole radiation of order $l$ (Equation 13) carries $l$ units (\hbar) of angular momentum per photon. Conservation of angular momentum and the notion that its couplings are vectorwise leads to the rule, Equation (19):

$$|I_i - I_f| \leq l \leq I_i + I_f$$  (19)

It thus appears that for certain spin combinations more than one multipolarity is allowed. In that case the lowest allowed multipolarity is the most probable one with mixing of the next higher one, for which $l$ is one unit larger. The parities of the initial and final states, $\pi_i$ and $\pi_f$, are also important for the electric or magnetic character. Conservation of parity, with $\pi_f$ the parity of the emitted $\gamma$-ray with multipolarity (angular momentum) $l$, leads to the rule, Equation (20):

$$\pi_l = \pi_i \pi_f$$  (20)

The parity $\pi_f$ of electric transitions is determined by Equation (21):

$$\pi_l(E) = (-1)^l$$  (21)

The parity $\pi_l$ of magnetic transitions is determined by Equation (22):

$$\pi_l(M) = (-1)^{l+1}$$  (22)

The consequences of the latter two rules are that electric transitions with even multipolarity $l$ and magnetic transitions with odd $l$ have even parity; thus $M_1$, $E_2$, $M_3$, $E_4$, $M_5$, $E_6$, and so on have even parity. Consequently $E_1$, $M_2$, $E_3$, $M_4$, $E_5$, $M_6$, and so on have odd parity. With the rules shown in Equations (19)–(22) and from the known spins and parities of the initial and final states the character of the radiation can be determined and thereby the probability of the radiation and its intensity as far as these factors are concerned. The following examples will illustrate the simplicity of the rules:

Transition $1^+ \rightarrow 0^+$ $M_1$ radiation only possible
$1^- \rightarrow 0^+$ $E_1$
$2^+ \rightarrow 0^+$ $E_2$
$3^+ \rightarrow 2^+$ $M_1, E_2, \ldots, M_4$. In practice only $M_1, E_2$ mixed.
$1^- \rightarrow 2^+$ $E_1, M_2, E_3$. In practice only $E_1, M_2$ mixed.

Note that the transition $0^+ \rightarrow 0^+$ cannot proceed via $\gamma$-radiation because the intrinsic spin of a photon is $1^-$. In this particular case the transition is fully converted to conversion electrons. All other transitions are also for a minor fraction converted, but the conversion coefficients are rather small, particularly for low multipolarity radiation and high transition energies. For instance, at $300$ keV for $E_1$ radiation the conversion is already below $1\%$, but for $M_4$ radiation, electrons and $\gamma$-rays have about the same probability. For further detail see, for example, Krane\(^{(14)}\) and Ejiri and de Voigt.\(^{(15)}\)

It should be realized that $\gamma$-rays generally are not emitted isotropically in space. Asymmetry can be as much as 50\%. The shape of the angular distribution depends on the angular momentum transfer in the reaction and on the population of the initial state and the final nucleus, as well as on the character (multipolarity) of the radiation. Quadrupole radiation, for instance, has its maximum along the direction of the beam, while dipole radiation peaks in directions perpendicular to the beam direction. For absolute values, measured angular distributions must be used or can be calculated on the basis of known
or assumed angular momentum alignments (see e.g. Krane(14)).

Finally, the energy shift and broadening of the $\gamma$-ray lines in the spectrum, which are due to the Doppler effect, should be mentioned. When a $\gamma$-ray is emitted during the flight of the excited nucleus through the sample or in vacuum behind the sample, the energy measured will be Doppler shifted. This is the case when the lifetime of the nuclear excited state is smaller than the average slowing down time of the recoiling nucleus in the sample. This time depends on the initial velocity of the recoil and on the slowing down material, but generally has values in the range of $10^{-8} - 10^{-14}$ s. The measured $\gamma$-ray energy is then given by Equation (23):

$$E_\gamma = E_{\gamma 0} + \frac{v}{c} \cos \theta$$  \hspace{1cm} (23)

where $E_{\gamma 0}$ is the unshifted energy, $\theta$ the angle of observation with respect to the beam direction and $v$ is the velocity of the recoiling nucleus. In the case of compound nuclear reactions the initial velocity can be calculated easily from Equation (6) as Equation (24):

$$\frac{v}{c} = 0.04635 \frac{\sqrt{m_2 E_p}}{m_2 + m_a}$$  \hspace{1cm} (24)

The masses are given in mass numbers and the energy in MeV, resulting in the ratio $v/c$. Almost all nuclear lifetimes of compound states, mostly highly excited states, are very short, of the order of $10^{-14} - 10^{-15}$ s. The corresponding de-exciting $\gamma$-rays are thus fully Doppler shifted and broadened, depending on the angle of emission and on the detector solid angle. Low-lying excited states may have much longer lifetimes and the corresponding $\gamma$-rays will not be affected by the Doppler effect. The resulting sharp lines are generally more useful for elemental analysis.

2.3 Principles of Depth Profiling

Charged-particle induced resonance reactions offer the possibility of obtaining the depth in the sample from which the $\gamma$-radiation is emitted and thus determining the depth profile of the elements. The leading principle is based on the fact that the beam particles are slowed down in the sample and thus the beam energy has to be increased to match the value of the resonance. The amount of increase $\Delta E$ (keV) depends on the depth $\Delta x$ (cm) and the two quantities are related via the stopping power $S$ (keV cm$^{-1}$) by Equation (25):

$$\Delta x = \frac{\Delta E}{S}$$  \hspace{1cm} (25)

In compilations (see e.g. Ziegler et al.\textsuperscript{(13)}) the stopping cross-section $\epsilon$ is often given in units of keV atom$^{-1}$ cm$^2$.

Here $\epsilon$ is defined by Equation (26) as:

$$\epsilon = \frac{\Delta E}{N\Delta \chi}$$  \hspace{1cm} (26)

where $N$ is the atomic density in the sample (at cm$^{-3}$). It should be noted that the depth resolution depends on the straggling in the sample, on the resonance width and on the spread in beam energy. It is therefore important to select resonances that are as narrow as the beam spread (keV).

Thus, the depth $\Delta x$ can be calculated from the difference between the resonance and the beam energy, the stopping cross-section and the atomic density. The atomic density can be expressed in terms of the mass density $\rho$ (g cm$^{-3}$) as Equation (27):

$$N = \frac{\rho N_{av}}{M}$$  \hspace{1cm} (27)

where $N_{av}$ is the Avogadro number $(6.022045 \times 10^{23}$ mol$^{-1}$) and $M$ is the molecular or atomic weight.

The stopping cross-sections are tabulated (for example in Ziegler et al.\textsuperscript{(13)}) for elements. In the case of a compound a simple rule called Braggs rule may be applied, Equation (28):

$$\epsilon = \sum_i c_i \epsilon_i$$  \hspace{1cm} (28)

where $c_i$ are the mass concentrations or the atomic fractions in a molecule.

3 PARTICLE-INDUCED $\gamma$-RAY EMISSION

3.1 Basic Principles of Particle-induced $\gamma$-Ray Emission

In PIGE, samples are bombarded with a beam consisting of light particles (protons, deuterons, tritons, $^3$He or $^4$He (\textit{a})) or heavy ions. The energy of the incident particles is usually in the range of 1–4 MeV amu$^{-1}$. The beam enters a vacuum chamber, in which the sample is placed, through a set of diaphragms and the emitted $\gamma$-rays are detected by, for example, a hyperpure Ge or Ge(Li) detector. The pulses from the detector are analyzed by a multichannel analyzer (MCA). A more detailed description of the experimental set-up can be found in section 3.5. A typical PIGE energy spectrum is shown in Figure 4.

This type of energy spectrum consists of a number of peaks corresponding to the $\gamma$-rays related to the elements present in the sample. These characteristic peaks are superimposed on a background that originates from Compton scattering of $\gamma$-rays in the detector. The number of counts in a peak of a certain element corresponds
to the amount of that element in the sample under investigation. All the parameters that determine the number of counts in a certain peak are known or can be measured. Using computer programs and databases, an absolute determination of the amounts of the elements in the sample is possible.

A complication in the spectra can be that the same γ-rays could result from two different reactions. For example, consider the reactions $^{26}\text{Mg}(p,\gamma)^{27}\text{Al}$ and the $^{27}\text{Al}(p,\gamma)^{28}\text{Si}$ which both give γ-rays with an energy of 843 keV and 1023 keV. Magnesium should then be identified by the $^{25}\text{Mg}(p,\gamma)^{26}\text{Mg}$ reaction which produces γ-rays of 586 keV. Aluminum can be identified by the $^{27}\text{Al}(p,\gamma)^{28}\text{Si}$ reaction with γ-rays of 1778 and 2836 keV.

Prompt γ-rays can originate from different types of nuclear reactions such as (p,γ), (p,αγ), or (p,γ) for protons, and (d,ny), (α,α′γ) and so on for other projectiles. When an element consists of more than one isotope, γ-rays can be produced in any of the isotopes and this will show up in the accompanying spectra as more lines belonging to one element but different isotopes. This leads to isotopic determination.

### 3.2 Possible Reactions and Their γ-Ray Energies

In a PIGE spectrum, the peaks are characteristic of different elements or even different isotopes of elements present in the sample under investigation. In Table 1, the most intense proton reactions together with the energy of the emitted γ-rays are presented for elements with $4 < Z < 20$. In Table 2, the most intense proton reactions for a number of heavy element isotopes are presented.

The elemental contents are obtained from isotopic contents, taking the natural abundances into account.

### 3.3 Sensitivity

A general discussion about the sensitivity of PIGE for different kinds of sample is difficult to give since it depends on the content of the major elements (the matrix), the minor elements and the trace elements in the sample. There are several ways to define the sensitivity of an analytical method.

The first and commonly used way to define sensitivity is by the minimal detectable concentration or limit of detection (LOD). It is defined by Equation (29)

$$\text{LOD} = k\sigma_b,$$  

(29)

where $\sigma_b$ is the standard deviation of the background under a (certain interval of a) peak of interest in a spectrum, and $k$ is a factor reflecting the desired confidence level.$^{(19)}$ It can be interpreted more easily with the help of Figure 5.

In this figure, the energy interval $\Delta E$ is taken as the detector resolution and is equal to the full width at half-maximum (fwhm) of the peak. $I_Z$ is the number of counts in the peak and $I_b$ is the number of counts in the background under the peak. Both are the number of counts in the energy interval $\Delta E$. The standard deviation $\sigma_b$ is taken to be the standard deviation of the background counts $I_b$. The confidence level $k = 3$, gives a confidence level of 99.98% for normally distributed measurements. This means that a peak is considered to be detectable if, Equation (30):

$$I_Z \geq 3\sqrt{I_b}$$  

(30)
Systematic studies concerning sensitivities have been performed by Deconninck and Demortier[5,6] with protons, Clark et al.[20] with protons and α-particles, Borderie et al.[19,21] with tritons and α-particles, Giles and Peisach[7] with α-particles and Borderie et al.[22] with heavy ions. Of about 70 elements studied, 40 can be determined with high sensitivity (≤100 ppm). Trace element sensitivity (ppm range) can be obtained for the light elements Li, Be, B, N, O, F, Na and P.(23)

In Figure 6, it can be seen that protons and α-particles are the best choice for the determination of light elements. Heavy ions can be used for the determination of medium and heavy elements at a level around 50 ppm. Accurate determination of concentrations in samples depends on the LOD and on the presence of major and minor elements in the sample. As a rule of thumb, accurate determinations can be performed at concentration levels around 10 times the LOD.

The second way to define sensitivity is to express it as the minimum absolute amount that can be detected. The absolute amount can be calculated from the concentration of an element if the areal mass density (g/cm²) of the sample is known. The minimal amount of light elements is in the range 10⁻¹⁰–10⁻¹¹ g. The lower limit in the absolute amount is obtained with the ion microprobe technique (see section 3.5). Here, a beam diameter below 1 μm can...

The third way is to use the thick-target yield (Equation 11) as a way to compare different elements, projectiles, energies and so on. The advantage of this method is that PIGE is most often used for the analysis of thick samples. A thick sample means a sample in which the incident particle is completely stopped. Generally, in thin samples the sensitivity is poor compared to thick samples. There is a strong energy dependence of the excitation curve, and the sample weight and composition should be known accurately.\textsuperscript{(25)}
Several authors have published tables with thick-target yields.\textsuperscript{(7,16–18,25,26)} Kenny et al.\textsuperscript{(25)} measured the absolute thick-target yield for several elements at incident proton energies of 2.0 and 2.5 MeV. They measured the yields for several $\gamma$-ray lines for elements ranging from F to Au. In Figure 7 the thick-target yield is plotted as a function of the atomic number $Z$ for the strongest $\gamma$-ray line of an element. It can be seen that the yield, and thus the sensitivity, is highest for the light elements.
Other datasets are presented by Anttila et al.\textsuperscript{(16)} and Kiss et al.\textsuperscript{(17)} They present thick-target yields for several proton energies between 1.0 and 4.2 MeV for isotopes with $4 < Z < 21$. Thick-target $\gamma$-ray yields for heavy elements ($Z > 30$) were determined by Räisänen and Hänninen\textsuperscript{(18)} for 1.7 and 2.4 MeV protons. Thick-target $\gamma$-ray yields for light elements with 2.4 MeV He$^+$ are given by Lappalainen\textsuperscript{(26)} and prompt $\gamma$-rays generated by 5 MeV $\alpha$-particles were investigated by Giles and Peisach\textsuperscript{(7)} who determined the sensitivity of elements ranging from lithium to hafnium.

In the following, a few examples of excitation curves (cross-section versus particle energy) for light elements will be given. In Figure 8 the cross-section for the $^{19}\text{F}(p,p'\gamma)^{19}\text{F}$ inelastic scattering reaction is given\textsuperscript{(27)} for four different $\gamma$-rays (109 keV, 197 keV, 1.24 MeV and 1.36 MeV).

For magnesium, excitation functions of $^{24}\text{Mg}$, $^{25}\text{Mg}$ and $^{26}\text{Mg}$ were determined by Boni et al.\textsuperscript{(28)} Taking into account the isotopic abundances, the 1369 keV $\gamma$-ray from $^{24}\text{Mg}(p,p'\gamma)^{24}\text{Mg}$ has the highest cross-section. As an example, this excitation function is given in Figure 9 for beam energies from 2.8 to 3.8 MeV.

A proper excitation curve is measured such that angular distribution effects are averaged out. For this purpose a large solid-angle detector is often positioned at an angle of $55^\circ$ with respect to the beam direction.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure9.png}
\caption{Excitation function for the $1369$ keV $\gamma$-ray from $^{24}\text{Mg}(p,p'\gamma)^{24}\text{Mg}$, $\theta_{\text{lab}} = 90^\circ$ (from Boni et al.\textsuperscript{(28)})}.
\end{figure}

3.4 Background

The LOD of an element can be calculated with the help of Equation (30) and is determined by the background radiation under the peak. The background can be caused by minor or major elements in the sample under investigation but also by the experimental set-up and/or the detector.

The background caused by the minor and major elements is dependent on the type and energy of the projectiles. The background is mainly caused by Compton scattering in the detector, depending on the response function and on the $\gamma$-rays reaching the detector. These $\gamma$-rays can be generated by competing nuclear reactions in the sample and in the surrounding materials.

$\gamma$-Radiation can also be produced by reactions taking place in the diaphragms in front of the vacuum chamber, the (aluminum) beam pipe, the vacuum chamber itself, and the Faraday cup used to measure the beam current. In the design of the vacuum chamber care has to be taken to use materials that do not produce large numbers of $\gamma$-rays. Light ions, particularly those induced by deuterons, cause more severe background effects than heavy ions. This is mainly due to the lower Coulomb barrier and to the many reaction channels that are open. Precautions have to be taken so that materials do not contain contaminations that can produce $\gamma$-rays.

Another problem could be natural radioactivity in the surroundings of the experimental set-up. Although the intensity generally is too low to be of any influence, in time-consuming experiments or in cases where a very low detection limit is required, this background can be of importance. To prevent any influence of the surroundings, lead shielding of the detector should be used. Aged lead exhibits less activity than new material.

3.5 Experimental Set-up and Procedures

In this section a typical experimental arrangement to perform PIGE experiments will be presented together with some experimental procedures.

3.5.1 Accelerator and Beam Guidance System

Most PIGE experiments on light elements are performed with energies between 1 and 4 MeV amu$^{-1}$. This energy is also ideally suited to performing simultaneous measurements with PIXE and/or RBS. In this case a single-ended Van de Graaff accelerator or pelletron accelerator is well suited to perform the PIGE experiments. If reactions are to be used where higher energies and/or heavy ions such as $^{15}\text{N}$ are necessary, tandem accelerators or cyclotrons should be used. In order for the accelerator to perform depth profiling, an easily changeable beam energy and
good energy resolution are required. This excludes a cyclotron for depth profiling, unless improvement of the beam quality is obtained, for example by means of a dispersive system.\(^{(24)}\)

Usually, the accelerator is connected to a so-called analyzing magnet which selects a beam with a desired energy for a specific ion. The calibration of the analyzing magnet is usually done by means of a suitable resonant nuclear reaction. Nonlinearity and hysteresis effects of the magnet can make the calibration procedure and the setting of the magnetic field to the correct value critical if great accuracy in the beam energy is required.

Sometimes a proton beam is used\(^{(29)}\) with an increased energy spread to make the excitation function more or less flat without any resonance structure. In this case it is not necessary to know the exact value of the beam energy from the accelerator.

The beam is transported to the irradiation chamber through evacuated pipes by means of bending magnets which bend the beam and electrostatic quadrupole lenses which focus the beam. The size of the beam on the target is usually in the range 0.5–5 mm in diameter but can be focused down to below 1 µm in a microprobe set-up.

### 3.5.2 Irradiation Chamber

Many possible layouts of the irradiation chamber are used to perform PIGE analyses. In Figure 10, a possible layout is presented where most of the commonly used features are included. The targets can be mounted on a one- or two-dimensional translation stage. This allows for multiple samples to be mounted and measured without breaking the vacuum by the application of micrometers or stepper motors. Moreover, the surface of the sample can be scanned if inhomogeneities in the sample are expected. One target position is mostly occupied with fluorescent quartz. It can be used to observe and align the beam spot on the target. For the majority of applications it is useful to be able to detect several types of radiation and particles from the sample. Besides a Ge(Li) detector to detect high energy \(\gamma\)-rays (PIGE), a Si(Li) detector to detect X-rays (PIXE) and a surface barrier detector to detect scattered particles (RBS) are usually mounted in the irradiation chamber.

For quantitative measurements, the beam charge can be determined in several ways. With thin samples in which the incident particles are not stopped, a Faraday cup behind the sample can be used to determine the beam charge accurately. With thick samples a rotating vane in front of the sample can be used or the beam charge can be determined from a beam current measurement from the sample itself. In all cases, care has to be taken to prevent secondary electrons from the target reaching the Faraday cup by applying secondary electron suppressor rings near the target and/or in front of the Faraday cup.

### 3.5.3 Detectors

The \(\gamma\)-rays in a PIGE experiment can be measured either by a scintillator (NaI(Tl)) or by bismuth–germanium–oxide (BGO), a Ge or a Ge(Li) detector. A detailed description of these detectors can be found in a textbook by Knoll.\(^{(30)}\) The NaI(Tl) detector has a relatively poor energy resolution (about 6% at 662 keV) combined with a high efficiency. It can be used in experiments where the energy resolution is not critical but efficiency is important, for example in depth profiling experiments where high efficiency is needed. BGO detectors have the advantage of a higher efficiency than NaI(Tl) for a given size crystal and a better peak-to-Compton ratio. The compact set-up makes BGO well suited to exploiting weak resonances. The superior energy resolution of a Ge detector (\(<2\) keV at 1.33 MeV), a relatively high efficiency and a large peak-to-Compton ratio means that the Ge detector is mainly used in experiments to determine the bulk concentration of complex samples. The energy resolution is high enough to distinguish \(\gamma\)-rays from competing reactions and to analyze interfering peaks in the spectrum. For low-energy \(\gamma\)-rays, use of a planar hyperpure germanium detector can be very useful.\(^{(23)}\) It has an energy resolution of about 500 eV at 122 keV.
3.5.4 Electronics

The detectors are connected to charge-sensitive preamplifiers and the resulting pulses are amplified in a spectroscopy amplifier. Shaping and filtering in these amplifiers are used to improve the signal-to-noise ratio. Next, the pulses are fed into a MCA. The analog-to-digital converter (ADC) part of the MCA usually has a resolution of 12 bit (4096 channels), although sometimes a higher resolution is used. The conversion time of the ADC has to be fast enough to prevent dead time problems, especially during high-count-rate experiments. Usually, a conversion time below 10 µs is applied.

3.5.5 Calibration and Spectrum Analysis

First, the γ-ray detection system has to be calibrated. This can be carried out quite easily by using a set radioactive source such as 60Co, 208Tl or 207Bi, depending on the energy region of interest. As an example, in Figure 11, a calibration spectrum is presented. Several peak-fitting routines exist to find the significant peaks and to determine accurately their (channel) positions in the spectrum. To analyze a spectrum, first the peaks have to be identified and possible overlap problems solved. The high energy resolution of a Ge(Li) detector and the limited number of γ-rays means that the peaks in a PIGE spectrum are usually well separated without overlap problems. The actual calibration is usually performed by fitting a linear (or higher) polynomial function between the energy of the peaks in the spectrum and their corresponding positions. The second step is to determine the intensities of the peaks. This is generally performed by a computer code. This computer code is usually also equipped with an automatic peak search algorithm making analysis of PIGE spectra easy to perform. Finally, the intensities of the peaks combined with a sensitivity calibration give the concentration of the isotopes present in the sample.

The precise beam energy has to be determined, particularly for depth profiling. This can be done by a number of reactions with narrow and strong resonances, depending on the energy of interest; e.g. the reaction 27Al(p,γ)28Si with a resonance energy of 991.90 ± 0.04 keV and 15N(p,αγ)12C with 429.57 ± 0.09 keV.

3.5.6 Target Preparation

Generally, the target preparation of PIGE samples is easy; just use them as they are. Some geological samples can be polished into sections, 20 µm thick, which allow investigation with an optical microscope. Powdered samples can be pressed into pellets and analyzed directly. Biological materials can be freeze-dried and measured. When liquids have to be analyzed, more complicated procedures have to be followed or an external beam has to be used (see below). In microbeam analysis, care has to be taken not to lose the integrity of the sample during preparation. In the analysis of light elements in biological samples this can be especially difficult to accomplish.

3.5.7 External Beam

Samples such as liquids, wet biological samples or objects with large dimensions cannot be placed inside an evacuated irradiation chamber. These samples can be analyzed with an external beam set-up where the beam exits the beam pipe through a thin foil which is often cooled. The sample is often placed in a helium atmosphere to decrease target heating and to increase the particle range of the protons (and thus diminish straggling) since stopping for hydrogen in helium is low.

3.5.8 Microbeam

A focused microbeam can be used to determine lateral distributions of elemental concentrations on a scale of about 1 µm. A microbeam set-up requires an object and aperture diaphragm combined with a number (2–4) of magnetic quadrupoles to focus the beam down to micrometer sizes. The focusing principles, problems, and applications can be found in a textbook by Watt and Grime.

3.6 Depth Profiling

Several isotopes have the potential for depth profiling, for instance 1H, 13C, 15N, 18O, 19F, 22Ne, 23Na, 24Mg.
PARTICLE-INDUCED $\gamma$-RAY EMISSION

$^{26}$Mg, $^{27}$Al, $^{29}$Si, $^{30}$Si. Most of these light nuclei have sharp and strong resonances in the excitation curve. The instrumentation for performing depth profiling is discussed in section 3.5. Additional requirements for the accelerator are a good energy resolution and the capability to change the energy easily. High-energy resolution of the beam is required in applications where narrow resonances are used. A detailed description of depth profiling can be found in Hirvonen.\(^{(31)}\)

4 APPLICATION OF THE PARTICLE-INDUCED $\gamma$-RAY EMISSION TECHNIQUE

Possible applications range from geological and archeological samples, steel samples, dust and aerosol samples to biomedical samples. In this section only a few examples are presented of PIGE analyses to serve as illustrations.

Van IJzendoorn et al.\(^{(33)}\) used the PIGE technique to quantify thin layers of SiF$_x$ that were a result of reactive ion etching of Si wafers with a CF$_4$ plasma. The quantification is important to understand the etching process. The $^{19}$F(p,p'\gamma)$^{19}$F reaction was used to determine F on the Si wafer. A proton energy of 2.78 MeV was chosen to suppress a Si reaction and thus limit the Compton background. An example of a $\gamma$-ray spectrum is given in Figure 12.

In Figure 13 an example of the analysis of a hafnium plate is presented.\(^{(18)}\) The hafnium plate is bombarded with 10 mC of 2.4 MeV protons. In the spectrum the following elements can be seen: O (150 ppm), Na (0.3 ppm), Al (30 ppm) and P (5 ppm). Also heavier elements including Zr (2.8%), Fe (100 ppm) and Cu (<50 ppm) can be observed.

Figure 12 $\gamma$-Ray spectrum of a 120-nm thick CF$_2$ layer on Si measured with 2.8-MeV protons (from van IJzendoorn et al.\(^{(33)}\)).

An example of depth profiling with the $^{15}$N(p,\alpha$\gamma$)$^{12}$C reaction is given in Figure 14. Here, the diffusion of 40 keV $^{15}$N in evaporation-deposited Ni was measured.\(^{(34)}\) The nitrogen segregates to the surface and to the Ni–Ta interface at increased temperatures. The nitrogen distribution is very narrow and the broadening is due to experimental resolution at this depth. This is clearly seen at the measured depth profiles.

5 CONCLUSIONS

We have shown that PIGE offers a simple, sensitive and quantitative multielemental analysis technique. With

---

Figure 13 $\gamma$-Ray spectrum of a hafnium plate after bombardment with 2.4-MeV protons. A lead absorber in front of the detector was used to decrease the low-energy $\gamma$-rays (from Räisänen and Hänninen\(^{(18)}\)). The annihilation peak is 511 keV.
Figure 14 $^{15}$N profiles in evaporated Ni on Ta after annealing. The original profile is that of the 40keV $^{15}$N implants (from Hirvonen$^{[31]}$ and Lappalainen and Anttila$^{[34]}$). The top layer of Ni is 370-nm thick. The measured $^{15}$N profiles show increased yields at the surface and at the Ni–Ta interface at increased temperatures (from Lappalainen and Anttila$^{[34]}$).

From the large number of analytical methods, activation analysis techniques are the only ones which are based upon nuclear reaction. The material sample studied is exposed to high-energy radiation which can be partly absorbed by a nucleus in the sample. Thus the nucleus is excited to a high energy level which can decay through quasi-prompt emission of a nuclear particle or photon. The product nuclide produced is mostly radioactive, and so emits delayed radiation. Both this and the aforementioned prompt radiation can be measured using appropriate radiation detectors. By evaluating the energy and the count rate of the particles detected, qualitative and quantitative analyses of the target material under study can be performed. Thus it is clear that elements only, not chemical species, can be determined directly. A large variety of particles can be used for activation, namely uncharged ones (neutrons, photons) or charged particles like protons, deuterons, tritons and even heavier ones. Mostly thermal neutrons from nuclear research reactors are used since this technique offers the highest average analytical sensitivity. During photon activation, the target nucleus is activated by photonuclear reaction. This is induced to “normal” material at high energies, usually not below about 10 MeV. The photonuclear reaction data of the elements suggest an activation energy around 30 MeV with respect to analytical sensitivity and interfering reactions, respectively. This energy is best achievable with bremsstrahlung sources like high-power linear accelerators or microtrons.
Favorable irradiation parameters are: 30 MeV electron energy at 100–150 μA mean electron beam current. With the help of suitable radiation spectrometers, e.g. high-resolution germanium detectors connected to appropriate pulse processing electronics, photon (γ or characteristic X-ray) spectra can be taken by which simultaneous multicomponent analyses can be carried out without chemical separations, sometimes even nondestructively. Moreover, partly extreme sensitivities can be achieved, and some elements can be analyzed whose determinations are difficult or impossible using other techniques, e.g. light elements like carbon, nitrogen, oxygen and fluorine. A further advantage is the relative freedom from blanks in many cases; after bremsstrahlung exposure, undesirable surface contaminants can be removed from the sample, and the recontamination that eventually occurs is inactive, and thus can be disregarded. Since the activation and measuring process is independent of the chemical status of the component studied, a large variety of matrices can be analysed. Photon activation has been applied in several areas including:

- geo- and cosmochemistry;
- environmental, biological and medical science;
- industrial product and high-purity material analysis;
- archaeological and forensic science;
- certification of reference materials.

The disadvantages of the method are common to all activation analysis techniques, e.g. the instrumental equipment costs. The cost of a high-performance germanium spectrometer is about US $30,000, and this does not include the permanent costs of maintenance and liquid nitrogen supply. Also, additional personnel qualifications are required for radioactive laboratory work. Finally, the handling of radioactive waste unavoidably produced during activation analysis might be problematic in some cases.

1 INTRODUCTION

1.1 Analytical Use of Electron Accelerators

Electron accelerators have been used not only for nuclear and particle physics but also in many other areas, such as in material, biological, geological and archeological sciences. In the analytical use of electron accelerators, photons such as synchrotron radiation and bremsstrahlung induced by high-energy electrons have been used more frequently than an electron beam itself.

Synchrotron radiation is generated by high-energy electrons circulating in the synchrotron. Synchrotron radiation energy is distributed continuously covering the infrared (IR) to X-ray region and interacts with molecules or atoms. In particular, the X-ray region of synchrotron radiation has been applied extensively to the field of analytical science using X-ray photoelectron spectroscopy (XPS), extended X-ray absorption fine structure (EXAFS), and X-ray fluorescence (XRF); these methods are useful to determine elements and their chemical states. Recently, many facilities using electron storage rings have been constructed for the exclusive use of synchrotron radiation.

However, bremsstrahlung is radiated in a forward direction of the electron beam when the electron is decelerated by Coulomb interactions in a material. Bremsstrahlung has a continuous energy distribution with a maximum energy equal to the electron acceleration energy. As the photon energy is significantly higher than that of synchrotron radiation, the bremsstrahlung photon interacts with the nucleus. The cross-sections of photonuclear reactions are about a hundred times larger than that of nuclear reaction induced by electrons of the same energy. Therefore, bremsstrahlung from high-energy electrons can well be used for radioisotope production and particularly for activation analysis. Usually, photon activation analysis (PAA) is carried out using an electron linear accelerator or a microtron which can supply mean electron beam currents of some tens to hundreds of microamperes at energies between 6 to say 60 MeV.

1.2 Principle of Photon Activation Analysis

In PAA, unknown samples are irradiated with high-energy photons. Then, radionuclides produced by photonuclear reactions in the sample (the (γ,n)-type reaction occurs most probably; see below, section 2) are identified by their radiation emission energy, and the intensity of radioactivity is measured. Each radionuclide represents an element originally present in the sample studied, and the intensity of radioactivity is proportional to the abundance of this element.

In general, unknown samples and comparative reference standards are irradiated simultaneously or sequentially, equipped with flux monitors. After correction of the activating photon flux received by the sample and the standard, respectively, the contents of the components of the sample can be calculated by the specific activity ratios of the sample and the comparative standard. Usually, a γ-ray spectrum of sample is measured with a high-resolution spectrometer as described below (see section 1.2.2). In the spectrum, the elements present in the sample are represented by respective peaks whose areas are proportional to the radioactivity of the element to be determined. The peak area ratio of the sample and the standard is commonly used for the calculation of the elemental content. In the following, the different radiation measurement devices commonly used in PAA are described briefly.
1.2.1 Scintillation Spectrometer

A scintillation detector consists of a large, cylindrical thallium (Tl)-doped NaI crystal which is shielded by aluminum housing (3 in. both in height and diameter being the standard size). Incident photon energy emitted from a radioactive sample is converted into visible light by the crystal. A photocathode plus photomultiplier (PM) tube is connected to the crystal. These convert the light flash into an electric pulse signal whose height is proportional to the absorbed photon-ray energy. These signals are processed further (amplified, reshaped and more) by a sequence of amplifiers (preamplifier, spectroscopy amplifier). The signals thus produced have values of several volts, depending upon the incident energy, are Gauss-shaped and short enough (4 \mu s in the normal approach) to enable undisturbed processing of high pulse frequencies, generated by higher activities of the measured material. The signals are processed further in a multichannel analyzer which produces a spectrum whose lines represent the respective energies emitted by the sample measured.

1.2.2 Coaxial Germanium Spectrometer

This device is used for high-resolution measurement of \( \gamma \)-rays. The basic set-up is similar to that of the NaI spectrometer described above. A high-purity germanium single crystal is applied instead the scintillation crystal plus PM tube. The other pulse-processing electronics are the same as described above. The resolution power exceeds that of an NaI spectrometer by about two orders of magnitude. Therefore, it is indispensable for the measurement of complex multicomponent spectra as mostly occur during instrumental multielement activation analysis.

1.2.3 Low-energy Photon Spectrometer

A low-energy photon detector (LEPD) is commonly used for detecting characteristic X-rays and \( \gamma \)-rays below 100 kV. The LEPD is made of a thin crystal of germanium (typically 10 mm thickness, 30 mm diameter). All the other devices in the spectrometer are the same as used in the coaxial spectrometer described above. The detection efficiency for X-rays is high, because X-rays are fully absorbed even by a thin crystal. Most of the photoactivation product isotopes of medium to heavy elements decay by electron capture (EC), because the \((\gamma,n)\) reaction products are mostly neutron-deficient nuclides. EC decay is always accompanied by characteristic X-ray emissions whose energies are those of the respective decay products. The \( \gamma \)-ray spectra of medium to heavy elements are often more complex than the X-ray spectra, as shown by Segebade and Weise.\(^{(1)}\) Therefore, low-energy photon spectrometry offers a complementary method to \( \gamma \)-ray spectrometry. The LEPD detection sensitivities for 36 elements were compared with that of a usual Ge detector.\(^{(2)}\) For quantitative analysis, self-attenuation of X-rays in a sample should be always estimated by the factor

\[
F(E) = \frac{1 - \exp\left(-\mu(E)d\right)}{\mu(E)d}
\]

where \( d \) is the sample thickness and \( \mu(E) \) is the total attenuation coefficient of the sample material at a given energy. Sato et al.\(^{(3)}\) carefully checked the self-absorption effect for the analysis of biological materials and the validity of the method was verified by analyzing several biological materials.

1.3 Short History of Photon Activation Analysis

The pioneering work on photonuclear reactions was done by Chadwick and Goldhaber\(^{(4)}\) in 1934. In this work, the photodisintegration of deuterons was induced by 2.62 MeV \( \gamma \)-rays from \(^{208}\)Tl as the excitation source. The radioisotope excitation method can only be applied to limited examples such as several isomers produced by \((\gamma,\gamma')\)-reactions and the photodisintegration of deuterium and beryllium.

Since 1950, electron accelerators have been constructed in many research institutions. These primarily served nuclear physics purposes, but an intense systematic study of PAA also began. In 1954, Basile et al.\(^{(5)}\) used a betatron for the determination of oxygen in organic acids. In the beginning, PAA was recognized as an analytical tool for light elements such as C, N and O, which cannot be determined by neutron activation analysis (NAA) using nuclear reactors.

First, Geiger-Müller counters were used for product nuclide radiation counting. In the 1940s, the energy resolution power of scintillation crystal detectors was recognized. Mostly Tl-doped NaI crystals were used for \( \gamma \)-counting, and they are still used for special applications (e.g. light element analysis).
